ABSTRACT

Testability issues concerning the need for including Design for Testability (DFT) techniques in VLSI designs are discussed. Types of fault models, the use of fault simulation and the DFT techniques of Scan Path and Built-in Test are described. An engineering methodology that uses the Genesil Silicon Compiler to produce a VLSI design, DFT_CHIP, which utilizes the DFT Scan Path technique is presented. Included are the procedures for using Genesil's simulation, timing analysis and automatic test generation features. The steps taken to fabricate the DFT_CHIP design through MOSIS are discussed. The methodology used to test the fabricated DFT_CHIP design on the Tektronix DAS 9100 tester is described. Appendix A and Appendix B provide copies of the Genesil check functions written for use during simulation on the DFT_CHIP design. Appendix C specifies the Genesil timing information for the DFT_CHIP design. Appendix D lists the conversion program which translates Genesil produced test vector files to the file format used during testing on the Tektronix tester.

I. INTRODUCTION

A. BACKGROUND

1. Testability Issues

Testability of VLSI (Very Large Scale Integrated) circuits deals with the issue of accomplishing measurements on a circuit to insure that it performs in the manner in which it was intended to perform. For a VLSI circuit to produce the "proper" or expected outputs several factors must be looked at. First, the circuit logic must be designed correctly to produce the desired outputs for a given set of inputs. Secondly, the chip must be physically fabricated properly so as to correctly implement that logic for which it was designed. Finally, the circuit should retain correct functionality over time by having stable operating characteristics. If proper engineering techniques were used to formulate the logic design for the circuits of a VLSI chip, the major testability issue centers on the ability to completely evaluate the physical functioning of circuits/gates internal to the chip. **Design for Testability** (DFT) is an approach to designing VLSI chips/circuits to better ensure that individual internal components can be accessed for testing purposes.

With future improvements of VLSI technology, the complexity (in terms of the number of components, gates, or circuits) of VLSI chips will continue to increase. As this

complexity increases, the degree of difficulty experienced during the testing of VLSI circuits will increase correspondingly. "Conventional" testing relies on adding additional mechanical means for testing such as extra input/output (I/O) pins for more test points, improving test fixtures, using additional testing probe points with a "bed of nails" etc., and suffers by being able to conduct testing only when the part is removed from the system it operates in [Ref. 1:p. 48]. In contrast, DFT relies on the addition of logic circuits internal to the chip to help facilitate testing and circuit accessibility, and DFT techniques can be used to design systems which allow in-system testing of parts [Ref. 1:p. 81].

Conventional testing methods have become inadequate primarily due to their inability to access internal circuit components and their need to feed signals through a test interface involving many I/O pins [Ref. 1:p. 57]. As VLSI chips become more dense they require extra pins for normal I/O operations thus leaving fewer pins which can be used for testing purposes. Also, with the increased miniaturization of VLSI chip circuitry, the number of pads available to connect to I/O pins has not kept pace with increases in the number of transistors within a chip [Ref. 1:p. 59]. When chip periphery lengths grow by Δl the area available for transistors grows by $(\Delta l)^2$ but the space available for pads grows by only $4\Delta l$. If this transistor growth requires more I/O pins and pad growth can not keep up, the pins available for testing will decrease.

The need for considering the inclusion of DFT techniques during chip design can be predicated largely on one factor: cost [Ref. 2:p. 100]. The need to insure reliability in a chip is self-evident and only testing can help insure reliability. If the cost of testing a complex VLSI chip is too great, an otherwise desirable logic design might not be produced. Although VLSI per circuit fabrication costs have been decreasing, the per circuit testing costs have increased as a percentage of the total chip cost as chips have become more complex [Ref. 1:p. 15]. Additionally, the costs associated with a user finding/using defective chips mandates that adequate testing be done prior to chips being distributed for use. To both lower the costs of performing testing and to allow a degree of testing in otherwise conventional testing prohibitive circuits, the inclusion of DFT criteria has emerged as a growing requirement in VLSI design.

2. Fault Models

The goal of DFT is to find ways to make testing easier, less costly, and more efficient to implement. By adding additional circuitry to the chip, DFT adds to the observability and controllability of the system. **Controllability** can be defined as the degree to which a node internal to a circuit can be set to a given logic level [Ref 3:p. 97]. In contrast, **observability** refers to the ability to observe the logic level of a given internal node via an output from the design [Ref. 3:p. 97]. The degree to which a chip can be

tested is highly dependant upon its degree of controllability and observability. By increasing the controllability and observability of a circuit, the testability, in terms of finding out if the circuit is "fault free", is increased.

A circuit is said to contain **faults** if it exhibits failures which cause deviations from the specified performance behavior [Ref 4:p. 1]. Two major classes of faults are design faults which manifest themselves as improper connections within the VLSI circuit and physical circuit defect faults such as those caused by manufacturing problems or wear out during chip operation [Ref. 4:p. 1]. Physical defects include open contacts, broken lines, faulty transistors, and shorts between parts of the circuit [Ref. 4:p. 1]. Photolithography errors during the manufacturing of VLSI circuits, such as alignment problems, mask failures, or unintended or missing connections, are major contributors to these physical defects [Ref. 5:p. 693]. Wear out failures can occur due to such things as metal starting to corrode or metal migration due to the presence of high current densities [Ref. 5:p. 695]. **Fault models** are used as a means for describing what the effects are of a particular type of circuit physical failure.

Fault models can include modeling faults down to physical defects at the individual transistor/switch level, but often fault models only consider faults down to the logic gate level. The advantage to using a logic gate level fault model is that this type of model can represent faults for many

different technologies. The **stuck-at fault** model is this type of logic gate level model and as such is the lowest level of modeling that is technology independent.[Ref. 6:p. 40]

The stuck-at fault model is based on assuming that physical defects causing faults will result in input or output lines of logic gates being permanently stuck-at logic level 0 or 1. As an example of how a stuck-at fault could be manifested in a CMOS circuit consider the inverter of Figure 1.1. If the line at point A is inadvertently shorted to ground then the output of the inverter will be stuck-at 1 (S-A-1) no matter what the input to the inverter is. If the line at point B is inadvertently broken then the circuit will produce the correct logic level 1 output when a logic level 0 is the input and the p-type transistor conducts. However, if a logic level 1 is the next input after a logic level 0 input the n-type transistor is not turned on because of the broken line. Instead, the output will remain at logic level 1 for a period of time which depends on leakage currents. If the inverter is included in a circuit which receives a high speed stream of inputs consisting of both logic level 1's and 0's then the time for the leakage current dissipation may be longer than the time between inputs of logic level 1's. If so, the output will appear as a permanent S-A-1 fault.[Ref 7:pp. 7, 8]

To illustrate how to test for stuck-at faults, the AND gate of Figure 1.2 is considered. If this gate has a S-A-1 fault at the gate's A input as shown, the gate will always

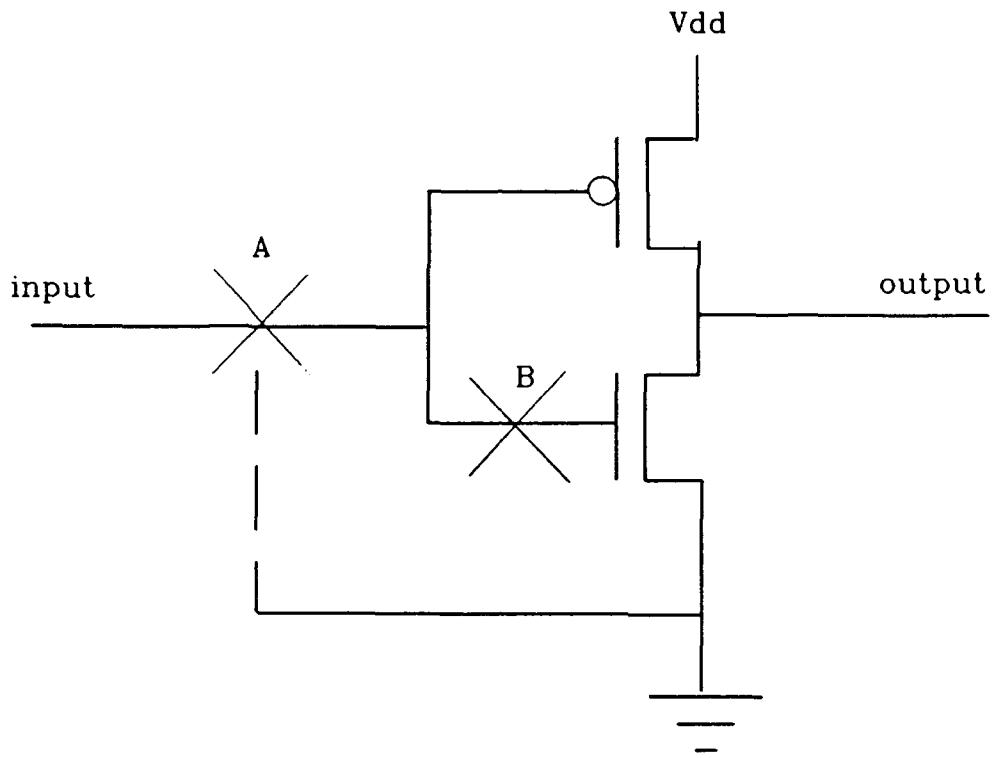

Figure 1.1 CMOS Inverter Stuck-at Faults After Ref. 7.

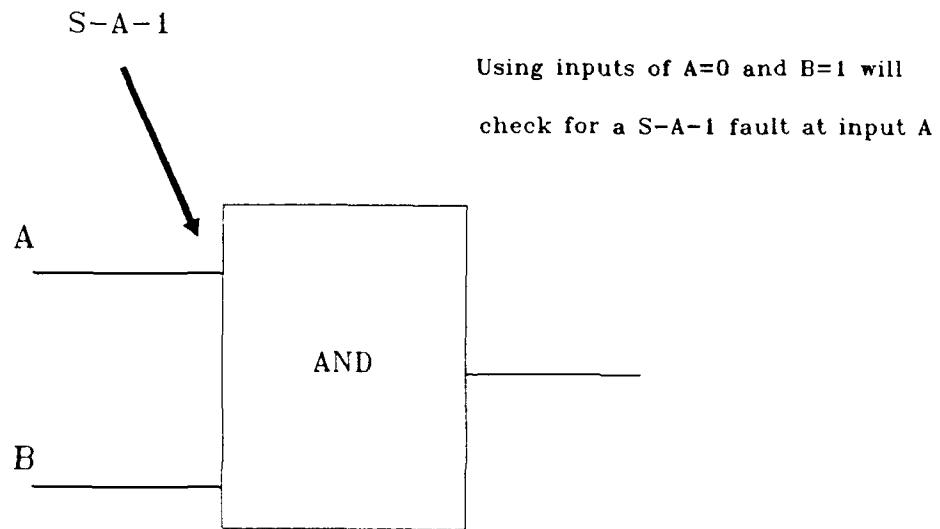

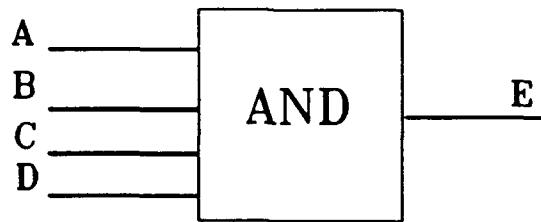

Figure 1.2 AND Gate Stuck-at Fault Testing

perceive line A to be at logic level 1, even if a logic level 0 is actually applied. To test for this S-A-1 fault for line A, note that the A,B input line pairs (0,0), (1,0), and (1,1) will all produce correct outputs on line C. Therefore, these inputs can not produce a result which indicates the presence of the S-A-1 fault. However, if input (0,1) is used the output should be logic level 0 but will instead be logic level 1 due to the S-A-1 fault at input A. Thus, the input pattern (0,1) is a test for a line A S-A-1 fault.

Each logic gate having a total combination of n input/output lines has a possibility of 2^n different single (one at a time) stuck-at faults (i.e., each input or output line can exhibit either a S-A-1 or a S-A-0 fault). One problem in testing is to design test vector inputs which can detect these 2^n stuck-at faults. The AND gate of Figure 1.3 shows that certain input patterns can determine the presence of more than one stuck-at fault. As an example, an A to D input line pattern of (1,0,1,1) which produces an output of logic level 1 means that either input line B is S-A-1 or output line E is S-A-1. As shown in Figure 1.3, only five test vectors are needed to completely test the proper functioning of this gate. Note that a test vector which produces an erroneous result will not be able to specify which stuck-at fault exists since each test vector covers more than one stuck-at fault case. Instead, the results from the application of the test vector will only indicate that the gate has

Figure 1.3 Test Vectors Needed for Stuck-at Fault Detection

a fault in it. However, this information alone is often all that is sought since then the VLSI circuit is known to be bad.

Although basically technology independent and widely used, the stuck-at fault model does have several problems. Among these are:

1. Only a single stuck-at fault is assumed to be present at a time in the VLSI circuit for this model type. Since more than one stuck-at fault could actually be present in a circuit, the stuck-at fault model does not accurately represent the true range of conditions possible [Ref. 8:p. 97].
2. The stuck-at fault model does not take into account high speed "AC" or "dynamic" type faults [Ref. 1:p. 403].
3. Certain types of faults such as bridging faults, involving shorts between lines, and floating-gate type faults can not be completely handled by the stuck-at fault model [Ref. 1:p. 404].

To overcome these problems other models such as the bridging fault model (a gate level model), and the stuck-open and stuck-on fault models (both transistor level models) can be used [Ref. 4:pp. 10, 11]. Today however, the single stuck-at fault model is still the model which is used most widely for testability and fault simulation purposes [Ref 3:p. 95]. The work done for this thesis is based on using a single stuck-at fault model.

3. Fault Simulation

In order to test a VLSI circuit a set of test vectors must be applied to the circuit and then the output results must be compared to the desired results (normally obtained from logic simulation). The purpose of **fault simulation** is to determine, for a specific set of test vectors, which faults in

the circuit are detected. Fault simulation normally involves a fault simulator introducing single stuck-at faults, one at a time, into gate level models of the circuit [Ref. 6:p. 37]. By then applying the test vectors to the simulated circuit, the fault simulator determines if the fault was or was not tested/detected. The result of fault simulation is a determination of the percentage of faults that were tested/detected with a given set of test vectors out of the total number of faults introduced by the fault simulator. Just because a fault is not detected does not mean that it is untestable; rather it just means that the given set of test vectors used could not detect it [Ref. 8:p. 97]. **Fault coverage** is the total number of faults, expressed as a percentage, that can be detected for a given set of test vectors as compared to the total number of all possible faults [Ref. 1:p. 335].

It is important to make a distinction between the two reasons and types of testing that is performed on a chip. Functional testing is used to validate the operational characteristics of a chip. Functional test vectors are applied to the chip and the outputs are observed to determine if they provide the results desired for a given input or sequence of inputs. In contrast, a set of test vectors which achieve maximum fault coverage is applied to a chip to determine if faults arising from the fabrication process are present. Therefore, the maximum fault coverage test vector set is not intended to check for proper design functionality

of the chip, but rather to check for manufacturing errors which result in faults that would preclude the chip from performing in its intended manner. Although technically possible, a set of maximum coverage test vectors is not normally used to check chip functionality because of the extreme complexity of determining the "proper" outputs (in terms of functionality) for the sequence of inputs that provides maximum fault coverage.

The question most frequently asked when performing testing is often "How much testing is enough?" A correlation has been found between fault coverage and average quality level (AQL), where AQL is a measurement of the percentage of defective parts found by users. Fault coverage must be very high to obtain an acceptably low AQL. A fault coverage of 50 to 70 percent produces approximately a five percent AQL, 90 percent fault coverage a three percent AQL, and it takes up to 99 percent fault coverage to get a 0.1 percent AQL. For an application specific integrated circuit (ASIC) 99.9 to 99.99 percent fault coverage is considered mandatory by many experts today. [Ref. 6:p. 37]

Of concern to a manufacturer of VLSI circuits is the defect level which is present for a given yield and percentage of fault coverage on a chip. A derivation, using the following steps as found in Ref. 8, produces an equation for the defect level in terms of these parameters:

1. Use the stuck-at fault model and assume all stuck-at faults are independent from each other.
2. Let P_n be the probability of a single stuck-at fault occurring on a chip which has n such possible faults. Let yield (Y) equal the probability of a good chip. Then since each fault is independent

$$Y = (1-P_n)^n. \quad (1.1)$$

3. Let A represent the case where the chip has no stuck-at faults on it. Let B represent the case where it is determined that no stuck-at faults are present in any of m sites that have been tested. Then the probability of B found from testing m out of n total possible faults is

$$P(B) = (1-P_n)^m. \quad (1.2)$$

4. The probability of A (probability of a good chip) given that B occurred (m of the sites were tested without finding a fault) is

$$P(A|B) = \frac{P(A \cap B)}{P(B)}. \quad (1.3)$$

5. Now $P(A \cap B)$ is $P(A) = \text{no faults on the chip}$ and $P(B) = \text{no faults at } m \text{ sites on the chip}$. If there are no faults on the chip there are also no faults at any set of m sites on the chip. Therefore,

$$P(A \cap B) = P(A) = (1-P_n)^n. \quad (1.4)$$

6. Let $DL = \text{defect level} = \text{probability that a defective chip is manufactured and sent to a user}$. $DL = 1$ minus the probability that a good chip is sent. Therefore,

$$DL = 1 - P(A|B) = 1 - \frac{P(A \cap B)}{P(B)} = 1 - (1-P_n)^{n-m}. \quad (1.5)$$

7. Substituting equation (1.1) into equation (1.5) gives

$$DL = 1 - Y^{(\frac{n-m}{n})} = 1 - Y^{(1 - \frac{m}{n})}. \quad (1.6)$$

8. Let $T = \text{fault coverage}$. Note that $T = m/n$ (i.e., testing m of n possible stuck-at faults). Then the defect level can be expressed as

$$DL = 1 - Y^{(1-T)}. \quad (1.7)$$

The graphical consequences of equation (1.7) can be seen in Figure 1.4. Note that even for high yields a very high fault coverage percentage is needed to get an acceptably low defect level. In a study conducted by Motorola, Published in IEEE Design and Test (April, 1985), using an actual manufacturing line with 50 percent yield, a fault coverage of 97 percent still produced a one percent defect level [Ref. 6:p. 40]. Figure 1.4 shows how equation (1.7) produces results which closely follow those obtained from this study even with the assumptions made about only independent stuck-at type faults being present on the chip.

The obstacle to using the fault simulation process is the time it takes to run a simulation evolution. Fault simulation time tends to rise exponentially as circuits become more complex [Ref. 9:p. 59]. This can lead to the inability to perform fault simulation, due to time constraints alone, on complex chips. Parallel or concurrent simulation algorithms which allow more than a single stuck-at fault to be examined during a given time period are alternative methods which can accelerate the simulation process [Ref. 6:p. 41]. Another method is via statistical fault grading which attempts to extrapolate the information gathered from a limited number of test vectors to predict overall fault coverage by factoring in information of controllability and observability. Although obviously not as accurate as complete fault simulation, statistical fault grading appears to be able to come within a

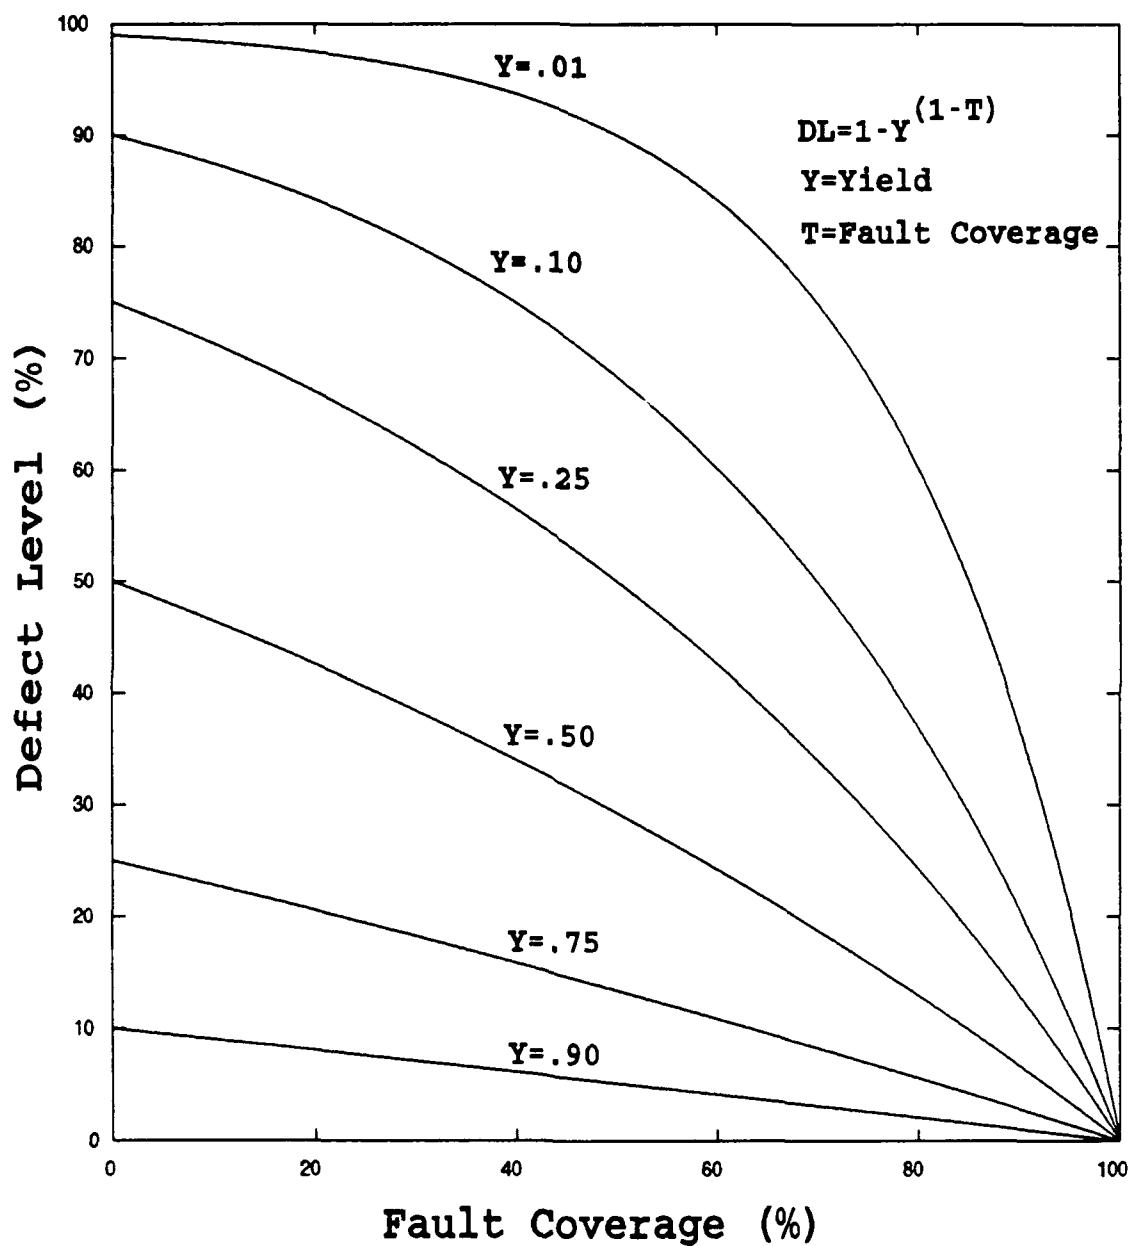

Figure 1.4 Defect Level versus Fault Coverage

few percent of the accuracy obtainable using complete fault simulation [Ref. 9:p. 59].

B. THESIS OVERVIEW

The primary goals of this thesis are twofold: first, to investigate the incorporation of DFT on a VLSI chip implemented on the Genesil Silicon Compiler; second, to use Genesil to design a chip with DFT features, have it fabricated, and physically test the chip. Through examination of the steps taken in working with an actual chip, this thesis will concentrate on the methodology for both incorporating DFT techniques into Genesil designs and for testing a fabricated Genesil implemented chip on a commercially available tester. Chapter II will describe the DFT techniques of Scan Path and Built-in Test. It will provide a comparison of the relative advantages and disadvantages of both these techniques. Finally, it will discuss the manner in which Genesil implements the Scan Path technique chosen for use on the chip which was fabricated was fabricated. Chapter III is concerned with the methodology process used during the design, simulation testing, test vector fault grading and automatic test vector generation for a 16-bit correlator chip produced using the Genesil Silicon Compiler. It will also include a complete functional description of this chip. Chapter IV provides information pertaining to the process of getting the chip fabricated via MOSIS and examines the methodology used and results obtained during testing conducted on the fabricated

chip. Chapter V provides a summary of and draws conclusions from the research done during the course of this thesis. The appendices provide copies of the programs and functions written to perform simulation on the correlator chip, information obtained about timing characteristics of the chip, and a copy of the program written to convert test vectors from the format provided by Genesil to that needed by the commercial chip tester.

II. DESIGN FOR TESTABILITY TECHNIQUES

A. BACKGROUND

The need for a high degree of fault coverage to insure a quality product has made it necessary to consider DFT issues while developing new VLSI designs. If internal circuit nodes cannot be initialized to needed test vector values (an issue of controllability) and/or the results of the tests cannot be seen (an observability issue) then the fault coverage possible will not be as high as is considered desirable. Only by including DFT circuit logic in a chip can observability and controllability be increased enough to raise fault coverage to acceptable levels for complex VLSI chips.

Two major techniques have evolved for incorporating DFT into chip design. The first is the **scan path** technique which involves the serial introduction of externally generated test vectors into specific internal nodes of a chip to enhance controllability and the serial extraction of internal node values from the chip to enhance observability. **Built-in Test** or **self-test** is the second technique. This technique uses additional circuitry on a chip to produce test vector patterns internally and may include circuitry to simplify the analysis of the test results. These two techniques can be used independently or both can be included in a single chip design.

Complementary Metal Oxide Silicon (CMOS) chips designed using Genesil may include either or both of these techniques. Genesil provides a **Testability Latch Block** which may be included in a chip design for the major purpose of increasing controllability and observability. For parallel datapath designs three configurations of the Testability Latch Block are available:

1. The basic configuration which uses a single shift register to serially enter or retrieve data.
2. The generator configuration which has the attributes of the basic configuration as well as including circuitry for pseudorandom test sequence generation.
3. The signature configuration which has the attributes of the generator configuration plus signature analysis logic circuitry.

The first configuration is used during implementation of the scan path technique while the latter two configurations make use of Linear Feedback Shift Registers to help implement the Built-in Test technique. [Ref. 10:p. 24-2]

B. COMPARISON OF THE SCAN PATH AND BUILT-IN TEST TECHNIQUES

1. Scan Path

The scan path technique is a conceptually easy approach to including DFT into a chip design. Scan path designs create a situation whereby access may be gained to the internal circuitry of a VLSI chip using a minimal number of chip pins devoted to testing. This technique enhances the observability and controllability of internal nodes which would otherwise be inaccessible from the periphery of the

chip. The scan path technique accomplishes this by partitioning a design into smaller subsystems which can then be tested to a higher degree and in an easier manner than the original system as a whole. A scan path is nothing more than a serial channel through which data can be shifted to reach flip-flops which provide a desired initialization state to specific internal nodes of the chip. Through the shifting process, specific values can be latched into the internal nodes prior to the start of a test ("scanned input") and the results can be shifted out after the completion of a test ("scanned output") [Ref. 1:p. 103]. Figure 2.1 illustrates the manner in which a generic circuit might be broken into smaller subsystems via use of the scan path technique. Thus, scan path solves the controllability problem via its ability to shift in data to internal nodes and solves the observability problem through its ability to access the results of tests by shifting them out of the chip.

The scan path technique is often used in connection with the flip-flops that already exist in a VLSI design due to the presence of sequential circuitry. This involves connecting the flip-flops which provide "memory" to the sequential circuit together in a controllable serial shift register type fashion. Then by using "switches" controlled by test signals, the flip-flops can be changed from the "normal" sequential circuit mode to a "shift register mode" in which the flip-flops form a shift register through which specific test

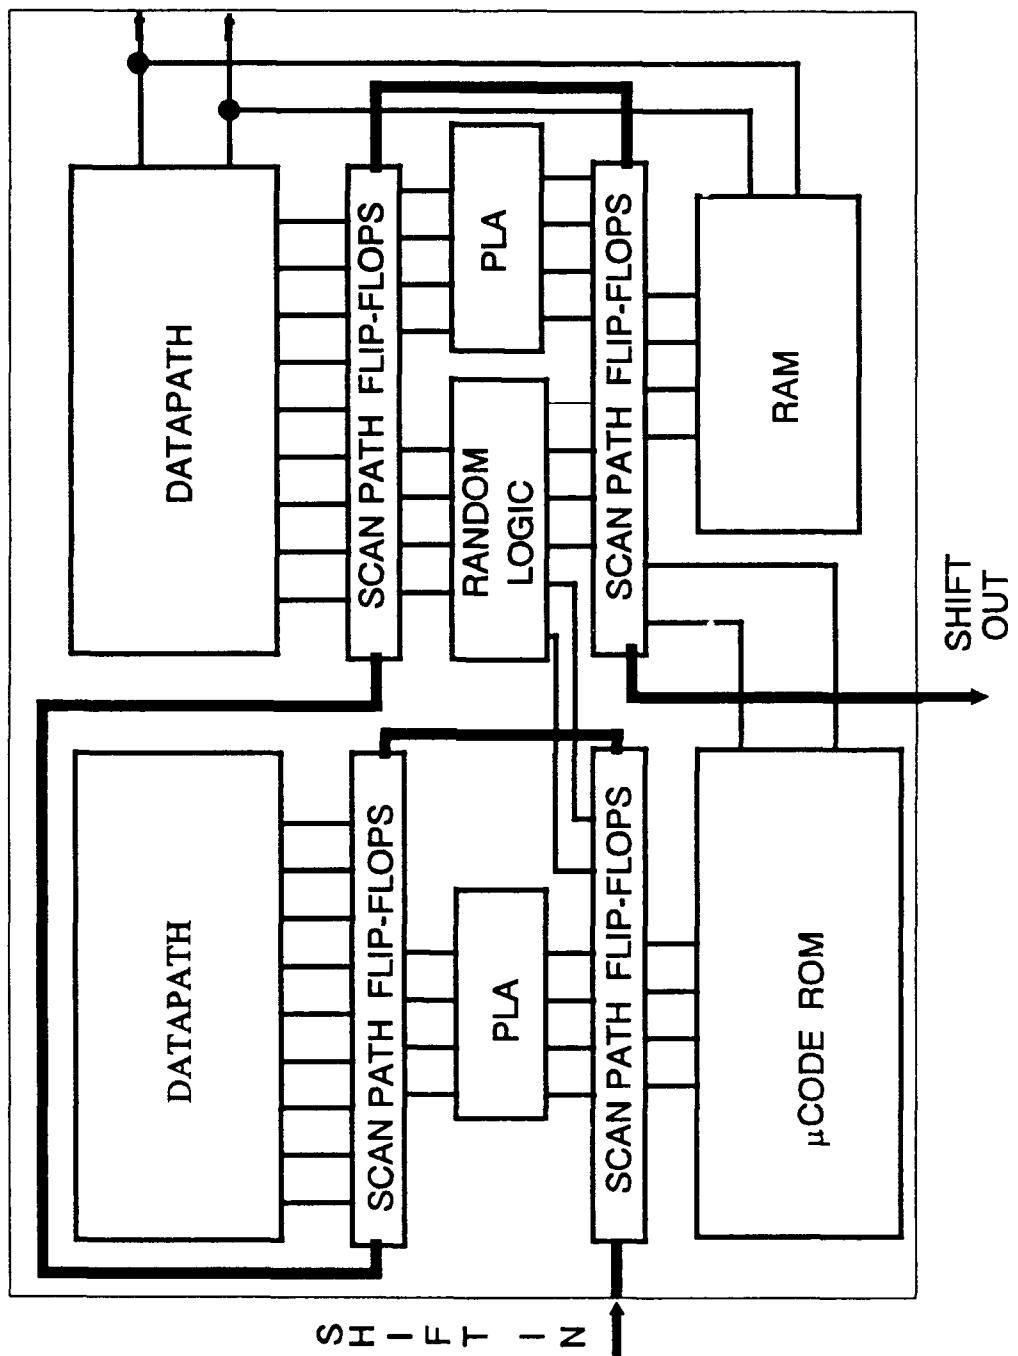

Figure 2.1 Circuit Broken into Smaller Subsystems
After Ref. 7

vectors can be introduced into particular locations of the circuit [Ref. 1:p. 108]. This makes possible the testing of the circuit. Figure 2.2 illustrates the process of introducing a scan path into a sequential circuit.

There are several individual and slightly different approaches which make use of the scan path idea. The actual **Scan Path** method chains together master-slave D type flip-flops to make the needed shift registers. These D type flip-flop-flops consist of two latches controlled by a single clock signal. The clock signal for the first latch goes through an inverter to become the clock signal for the second latch. The disadvantage to this approach is that if the input to the D flip-flop changes at nearly the same time that the clock does or if the output of the second latch feeds back through combinational logic to become the input of the first latch then a race condition could exist.[Ref. 2:p. 105]

To overcome this potential race problem an approach called **Level Sensitive Scan Design** (LSSD) was developed. It utilizes the same basic idea as Scan Path for moving test vectors into and out of the circuit but uses two separate clocks, each controlling a separate latch from a two latch pair. By using two separate clocks to control a latch pair element of the shift register, the LSSD technique overcomes the potential race problem present for the Scan Path technique.[Ref. 2:p. 105]

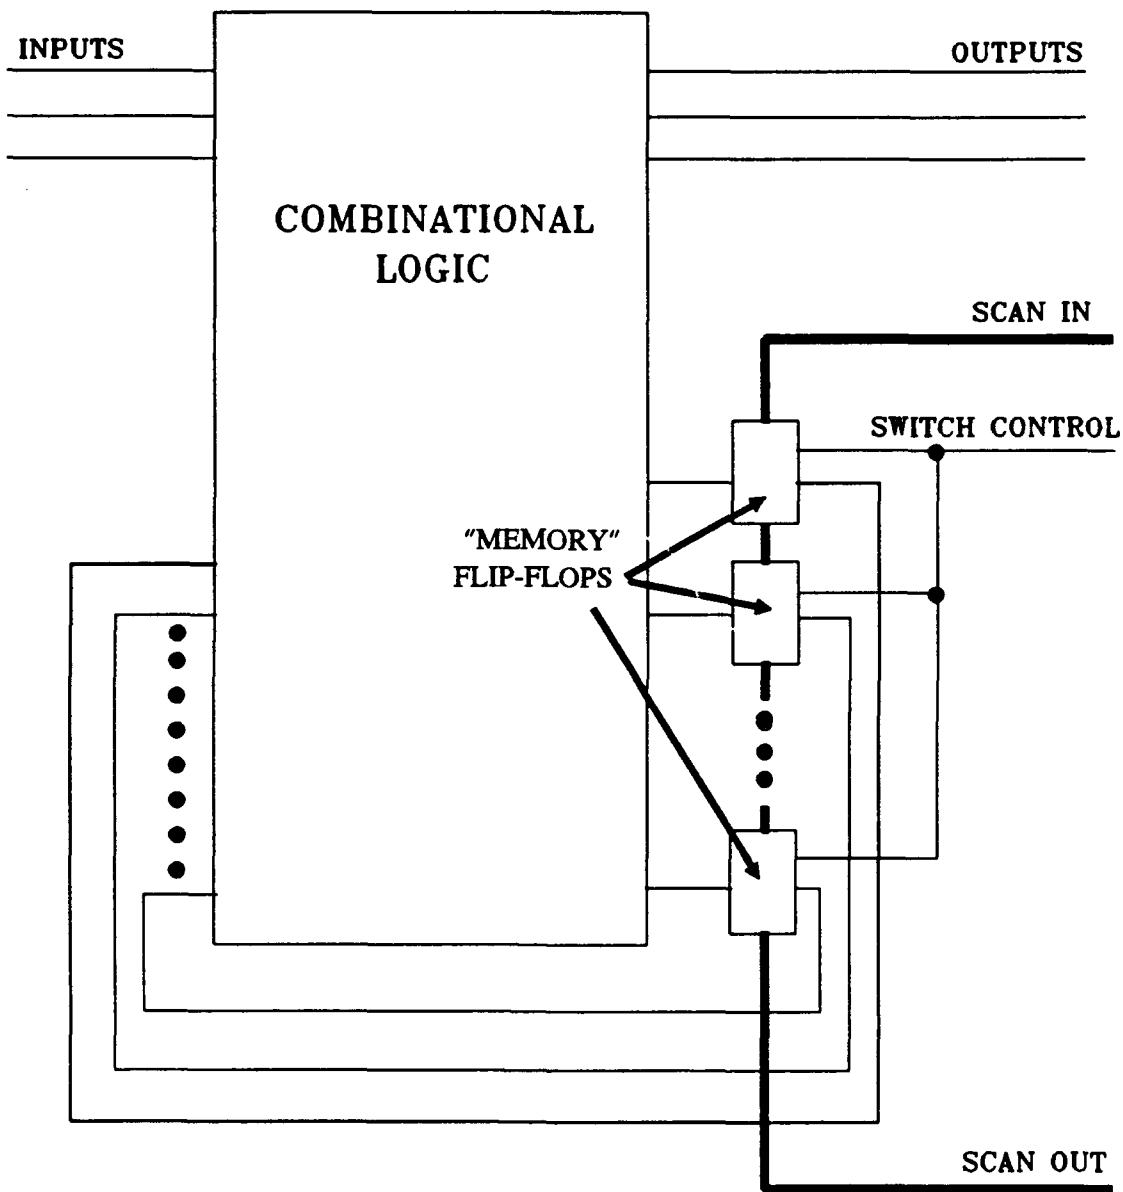

Figure 2.2 Using a Scan Path in a Sequential Circuit

Finally, a related method which has been developed is the **Scan Set** method. This technique varies from straight scan path methods in that although it uses shift registers, they are not located in the data path. Instead, the shift registers are placed adjacent to the circuit's own sequential circuit latches. There are two advantages to this method. First, a designer can determine exactly which of the sequential circuit latches he desires to have the ability to set if the ability to set all latch points is not needed or desired. Secondly, Scan Set sampling can occur during the sequential circuit clocking period thus providing a snap shot of the sequential circuit during operation. [Ref. 2:p. 106]

2. Built-in Test

The Built-in Test (BIT) technique is inherently more complex than the scan path technique. BIT involves a tradeoff of additional chip circuitry above that used in the scan path technique against the ability to internally generate test vector patterns and compact test result responses. This facilitates the testing procedure by moving a portion of the test process from off to on chip. The scan path technique needs to scan-in a test vector and or scan-out a test result for each test cycle. In contrast, BIT reduces the need to scan-in a new test vector for each test cycle since it internally generates its own test vector patterns after an initialization process. Additionally, BIT can reduce the need to scan-out test results each test cycle by encoding the

results in a more compact form which need be looked at only after the completion of a large number of test cycles. The combination of these two effects results in BIT allowing multiple test cycles to proceed at full system speed with only the overhead of single initialization and final result gathering phases to slow it down.[Ref. 1:pp. 169, 170]

The use of a structure called a **Linear Feedback Shift Register** (LFSR) is the main method which has been developed to provide internally generated test vector patterns. The patterns which are produced are normally deemed to be **pseudo-random** in nature since they follow no apparent order from pattern to pattern and meet some basic statistical tests for randomness. In reality they are not random, thus the designation pseudo, but rather follow a predetermined sequential order which depends both upon the implementation configuration of the LFSR and upon the initialization values place in the flip-flops of the LFSR.[Ref. 1:p. 172]

The basic structure of a LFSR as implemented by Genesil is shown in Figure 2.3. It consists of an n-stage shift register with each stage position serving as a latching mechanism for a single bit. The multiplexer control line R determines whether the input for the bit zero stage position comes from the feedback loop or from the serial input line TIN. Initialization is provided to the LFSR by serially loading a desired value into each shift register bit stage position. Once initialization is complete the control line R

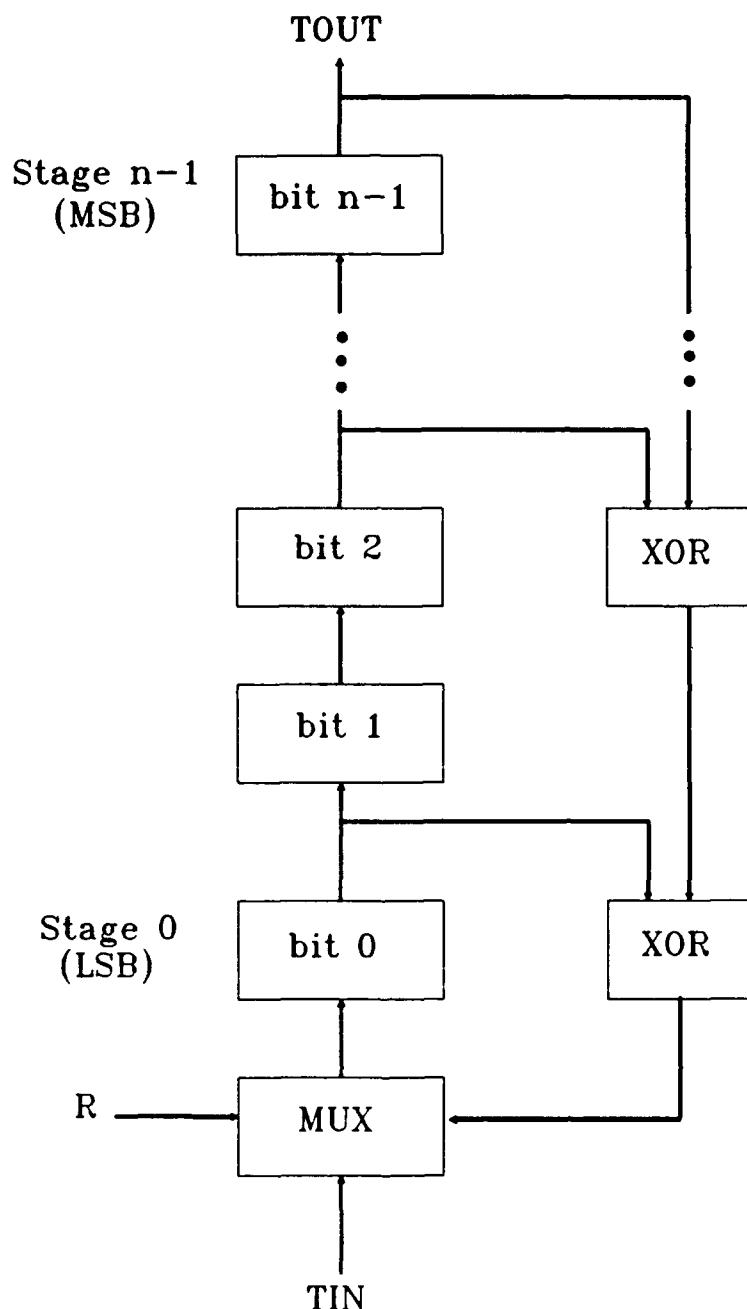

Figure 2.3 Linear Feedback Shift Register After Ref. 10

can be set so that the bit zero stage position accepts values only from the feedback path. The changing contents of the LFSR bit stage positions will produce a pseudorandom sequence determined by the specific locations where exclusive-or (XOR) gates are found in the feedback path. By taking the output from each bit stage position and forwarding it to other circuit logic on the chip a sequence of internally generated test vector patterns is produced by the LFSR.

The locations where XOR gates are present in the feedback path is dependant on a constant called the LFSR polynomial which determines the number of terms between repetitions in the pseudorandom sequence [Ref. 7:p. 66]. It is desirable to have both the number of terms produced by the pseudorandom sequence generator be of maximum length and to utilize a minimum number of XOR gates in the feedback path. A maximum length sequence generator from an n -stage LFSR can produce $2^n - 1$ different sequence terms [Ref. 1:p. 175]. Reference 8 provides a detailed discussion on the development of LFSR polynomials which minimize the number of XOR gates needed to achieve a maximum length generator sequence for a given size n -stage LFSR.

A modified LFSR structure may be used to form a **signature analysis** register as shown in Figure 2.4. The signature analysis register is formed by adding an additional XOR gate as the last item in the feedback path to perform an XOR operation on the feedback path value and an incoming data bit

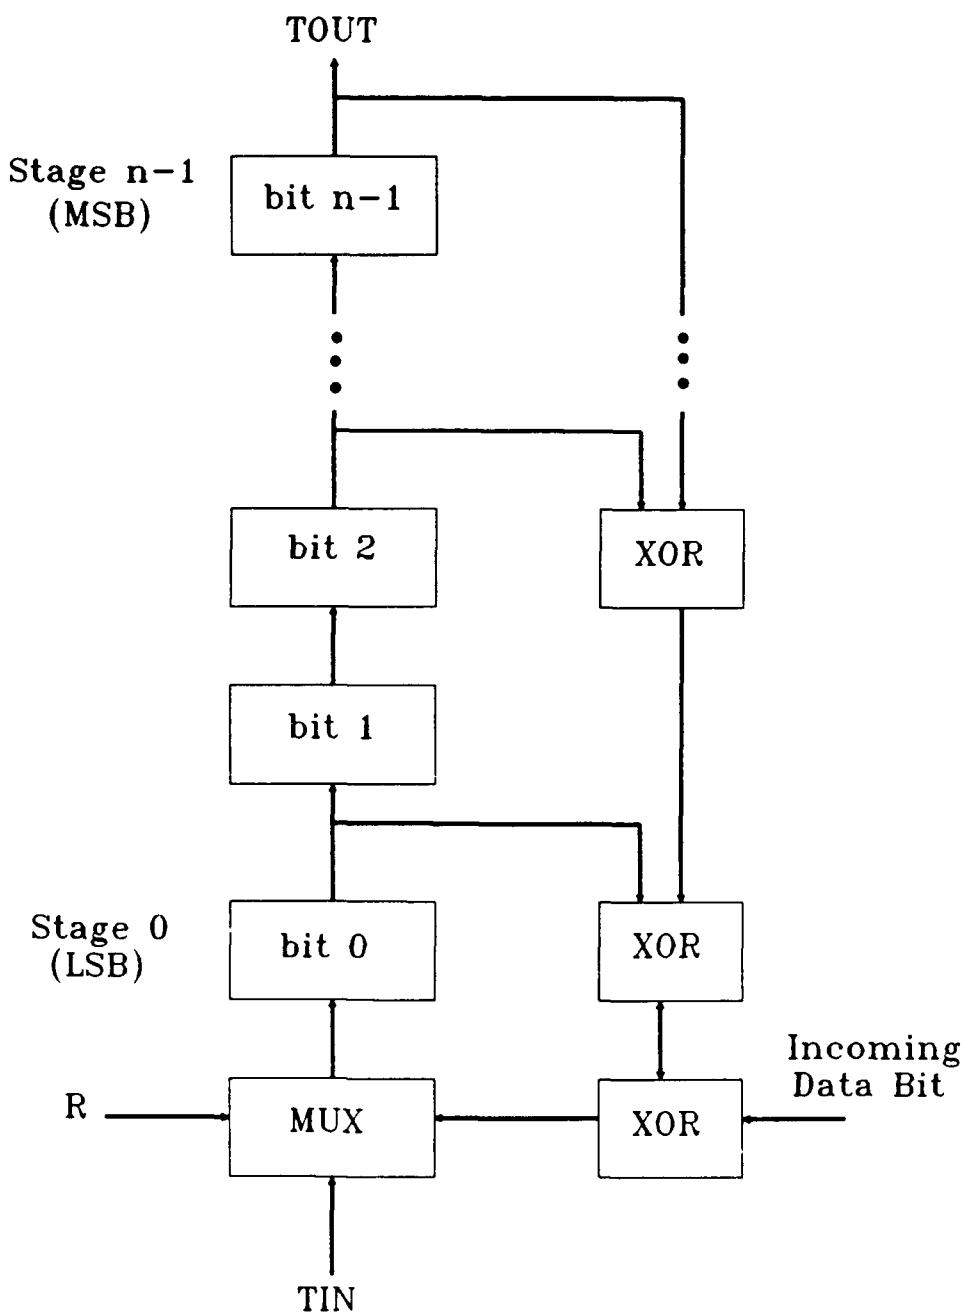

Figure 2.4 Signature Analysis Register

value [Ref. 8:p. 143]. Therefore, the pattern present in the signature analysis register is dependant on the initialization vector loaded serially into the shift register, the XOR gate structure of the feedback path, and the data sequence occurring for the incoming data bit. If the signal analysis register is initialized with a known value and the incoming data sequence is also known then the pattern which should be present in the shift register portion of the signal analysis register after a specific number of clock cycles can be determined through simulation.

Placing a signature analysis register on an output line of a circuit being tested allows the output test sequence results for a large number of consecutive tests to be compacted to a shorter cumulative sequence. Thus, the signature analysis register serves to encode the test result sequence. The encoded, cumulative results can be shifted out to compare against simulated results obtained by using the output data sequence from a properly functioning circuit. If the results vary between the two cases then a fault in the circuit has been detected.[Ref. 1:p. 177]

Built-in Logic Block Observation (BILBO) is a BIT method which is similar to the signature analysis approach. The BILBO structure differs from a signature analysis register mainly in that it has available additional XOR gates placed before each bit position to allow a total of n incoming test data bits to influence the encoded BILBO register value

[Ref. 8:p. 144]. Therefore, BILBO is well suited for compacting test results obtained from multiple internal nodes in a chip.

A general strategy for utilizing BILBO is shown in Figure 2.5 and Figure 2.6. Figure 2.5 shows the configuration used to test the first combinational logic block. Figure 2.6 shows the shifted configuration used to test the second combinational logic block. BILBO registers are ideal for this setup since if their test data bit input lines are held constant they can function as a LFSR test pattern generator and otherwise they can function as a test result compactor. By shifting the function performed by the two BILBO registers both sets of combinational logic can be adequately tested.

[Ref. 2:p. 107]

3. Comparative Advantages and Disadvantages

a. Scan Path Advantages

The primary advantage in using the scan path technique is that it increases both the controllability and observability of otherwise inaccessible internal nodes. In doing so it raises the obtainable fault coverage level possible for a chip. Using a scan path makes possible the introduction of a minimal number of specifically designed test vectors to maximize the fault coverage [Ref. 11:p. 379]. Using these customized test vectors may in some circumstances reduce the total number of test vectors, as compared to the

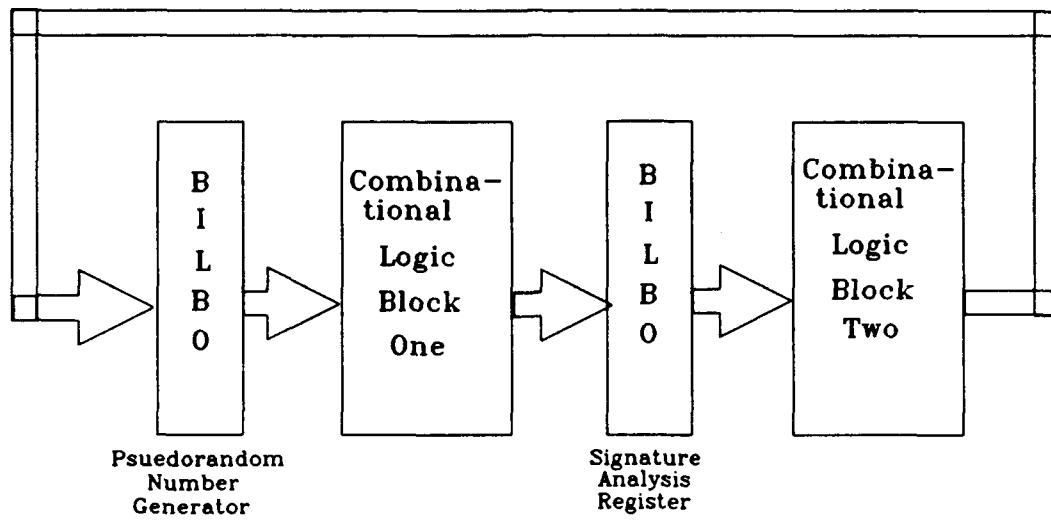

Figure 2.5 Configuration to Test Combinational Logic Block One After Ref. 2

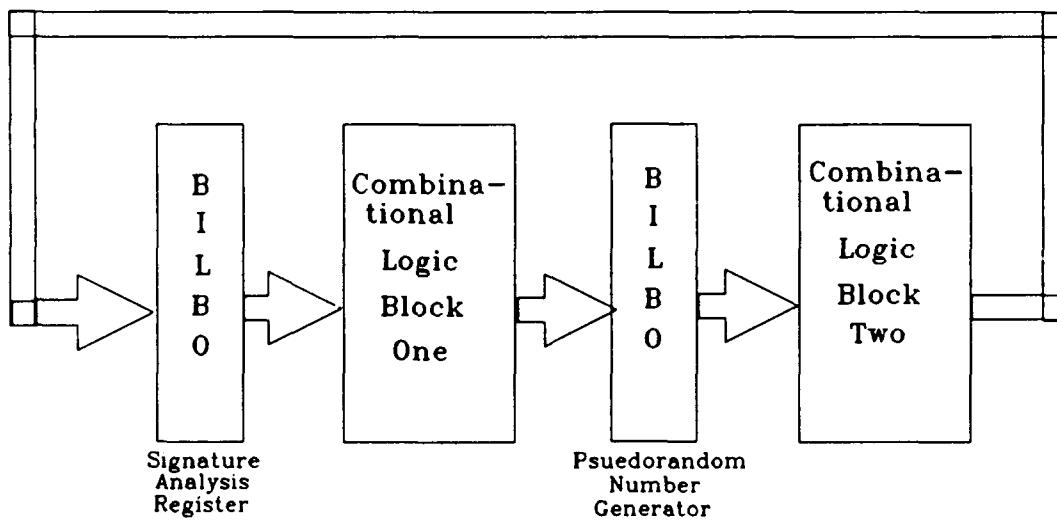

Figure 2.6 Configuration to Test Combinational Logic Block Two After Ref. 2

BIT technique, that need to be scanned in to achieve a desired fault coverage level [Ref. 7:p. 93].

b. Scan Path Disadvantages

The disadvantages of the scan path technique are related to both external test gear complexity and cost and to the time needed to perform adequate testing. Since all test vector inputs and test result outputs are generated or examined external to the chip, a complex, costly test gear setup is normally needed [Ref. 7:p. 94]. This test gear must be able to both generate and apply the customized test vectors required and then analyze the test results for each test vector input used. Thus, the test gear must work with a much larger volume of data than if the BIT technique is used.

The need to both load each test vector input and extract each test result output in a serial manner can involve a significant overhead of time. Desired testing may take a significantly large number of clock cycles and the testing time overhead will increase with the length of the scan path used. Also, the time overhead involved to utilize a multiple number of test vector patterns is much greater than if BIT, which needs only a single shift-in and shift-out of data for a set of multiple test vector patterns, is used.

c. Built-in Test Advantages

A main advantage of the BIT technique is that it allows a portion of the test functions to be moved from off to on chip. This may make the use of simplified external testing

processes or test gear possible. By generating test vector patterns and compacting test results internally, BIT can greatly reduce the volume of data which needs to be shifted in or out of the chip [Ref. 2:p. 108]. Finally, by combining this lowered overhead with an ability to generate and apply the internally generated test vector patterns at the rated speed of the chip BIT can greatly reduce the total time spent in applying a specific number of test vector patterns to the chip [Ref. 11:p. 379].

d. Built-in Test Disadvantages

One potential disadvantage of using BIT is encountered when either signature or BILBO registers are used to accomplish test result compaction. This problem is termed **aliasing**. Aliasing refers to the situation where the encoded result produced in the signature analysis or BILBO register for a faulty circuit is the same as that produced for a fault free circuit. This occurs when the test data streams for a faulty circuit and fault free both compact to the identical encoded result. The probability of aliasing occurring is a function of the number of bits compacted from the test data stream versus the number of stages in the register. This probability will rise if either the number of bits to be compacted is increased or if the number of stages in the register is decreased.[Ref. 8:p. 106]

A second major disadvantage for BIT centers on the test vector patterns which can be generated by a LFSR network.

Although a LFSR maximum length sequence generator can produce a nearly exhaustive, $2^n - 1$ set of test patterns for an n -stage LFSR, the sequence order of the test patterns produced may be nonoptimal for achieving a maximum level of fault coverage [Ref. 11:p. 379]. It is possible that there may be no initialization pattern which can be applied to the LFSR to produce a properly sequenced set of test patterns to maximize the fault coverage.

A final disadvantage is that BIT requires additional circuit logic above that needed for the scan path technique. A multiplexer is needed to control the flow of data into the shift register chain and XOR gates are needed both in the feedback path and for the any entry points of test result data which is going to be compacted. The cost of this additional circuit overhead can be looked at in terms of the ratio of circuitry needed for testing to that of the circuitry needed for performance of the chip's required functions.

C. GENESIL IMPLEMENTATION OF THE SCAN PATH TECHNIQUE

The device used during this thesis to investigate the incorporation of DFT into chip design is a 16-bit correlator. It was chosen because it involves an easily understood functional design which can readily incorporate DFT. Additionally, this design was chosen because consideration of DFT issues for it had already been looked at in previous thesis work by Davidson [Ref. 7]. The goal established for the chip design which was fabricated was to incorporate that DFT

technique which would maximize fault coverage for a minimum number of applied test vector patterns. Based on the results and conclusions in Reference 7 about this correlator design, the scan path technique was chosen as the method to use to accomplish the chip design goal.

Implementation of the scan path technique for a Genesil produced design is accomplished by including Genesil Testability Latch Blocks. These blocks consist of a set of serially connected, individual **testability latches**. Each testability latch operates on a single bit of data. By stringing the testability latches together serially a scan path shift register channel is produced. The Testability Latch Blocks have the ability to perform five different operations:

1. During normal (nontest) operation of the chip they serve as data storage latches.
2. The **shift** operation provides the ability to serially load or extract a test vector via the scan path. Each shift operation moves the scan path shift register data one bit further along the scan path in the direction towards the scan path output.
3. The **force** operation is used together with the scan-in process. It provides the ability to take a test vector which was serially loaded into the scan path shift register and force a parallel load of its values into the data storage latches.
3. The **sample** operation is used together with the scan-out process. It causes the values in the data storage latches to be loaded in parallel into the shift register. Values can then be serial shifted out of the chip.
4. The **swap** operation makes possible coupled force and sample operations. The result is that sampled data can be removed from the data storage latches and shifted out at the same time that a new test vectors is shifted in.

Through these five operations Testability Latch Blocks are able to enhance controllability and observability within a chip design.[Ref. 12:p. 15-2]

The circuit configuration of a single testability latch is shown in Figure 2.7. Five control gates and three D type transparent latches are used in the testability latch circuit. The control gate signals LOAD, A, B, F and S both enable the gates so as to route data between the latches and provide the signals which cause the latches to be loaded. Latch D serves as the data storage node and is loaded when either the LOAD or F signal goes high. Latches S1 and S2 form the shift register. Latch S1 is loaded when either the A or S signal goes high. Latch S2 is loaded when the B signal goes high. To form a complete scan path the TOUT signal from each testability latch is connected to the TIN signal of the testability latch for the next-most-significant bit. Only the TIN signal for the least-significant bit (LSB) and the TOUT signal for the most-significant bit (MSB) of the scan path need to be connected to external pins on the chip.[Ref 12:pp. 15-3, 15-4]

The functions performed by the testability latches are based on the control gate signal sequences introduced to the circuit. To load the data storage latch with the value present on the DIN signal line the LOAD signal must be raised high. The latched data value then becomes available on the DOUT signal line. To shift data upwards one significant bit in the scan path shift register the control A and B signals

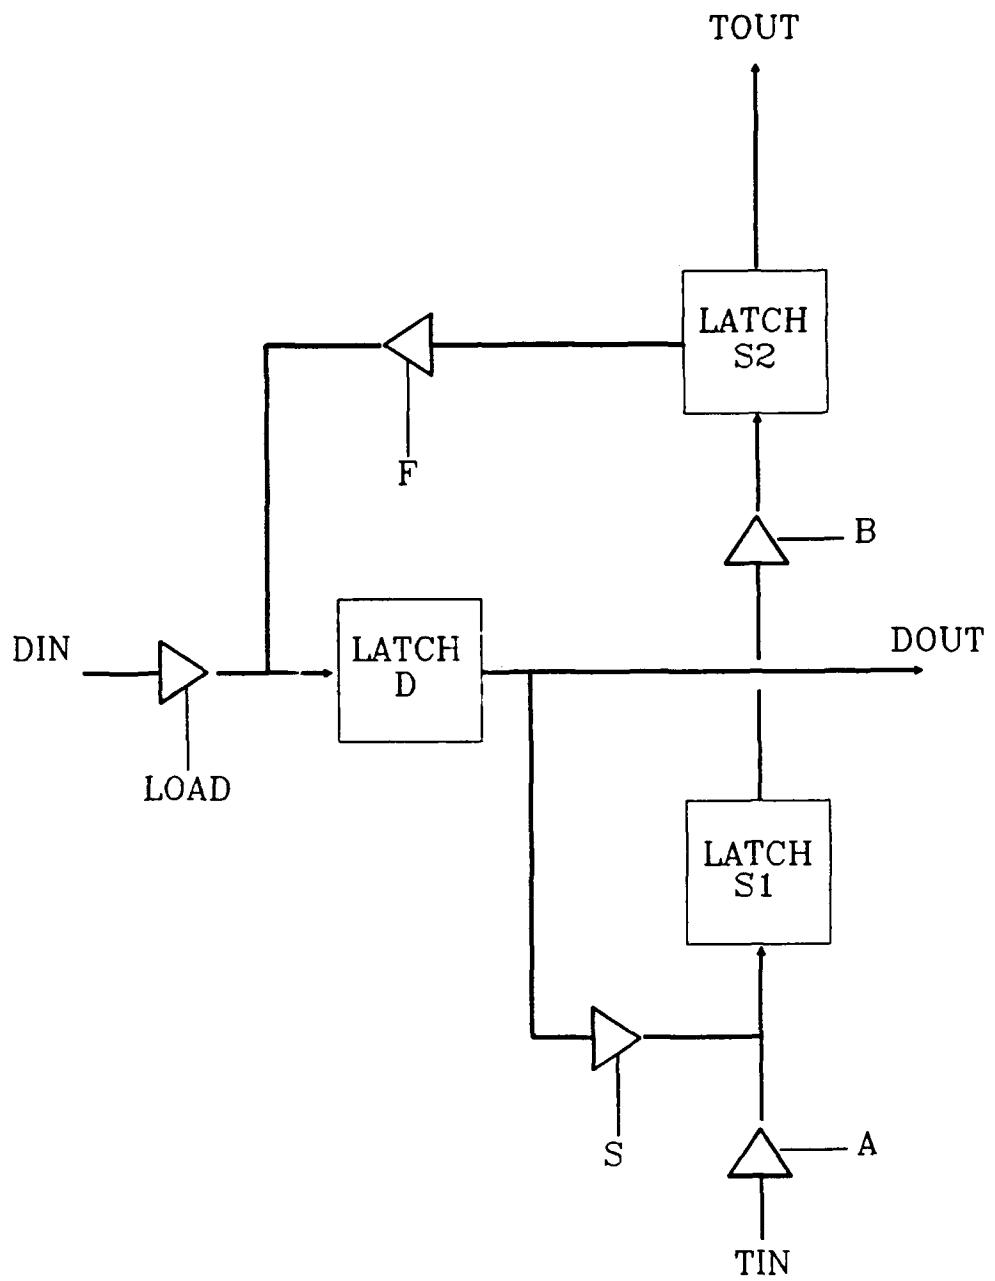

Figure 2.7 Testability Latch Circuit Configuration
After Ref. 12

must be sequentially strobed. To force data to be copied from the scan path shift register to the data storage latch the control F signal must be strobed. To sample or copy data from the data storage latch to the shift register the control S and B signals must be sequentially strobed. To swap or exchange data between the shift register and the data storage latch the control S, F, and B signals must all be sequentially strobed.

[Ref. 12:p. 15-5]

In Genesil, using random logic blocks, there are three configurations of basic testability latches available. Their differences are based on the methods used to provide clock and control signals to the testability latches. These three configurations are:

1. The **TLATCHU** configuration. This configuration uses unclocked A, B, F and S control signals which function independently of any clock signals found on the chip. It requires that externally generated control strobes be used to drive the A, B, F and S control signal lines directly. Typically these control strobes originate from off chip. The chip designer must ensure that the timing sequence requirements for the control signals are met to perform the desired operations. Table I specifies the different operation modes of the TLATCHU configuration.[Ref. 12:p. 15-6]
2. The **TLATCHG** configuration. It makes use of the phase_a and phase_b clock signals derived from the two-phase global system clock to implement timing relationships used in producing properly timed control sequence orders for the A, B, F and S control signals. Input control signals named M1 and M2 are used to encode the operation which is desired for the testability latch. These signals are latched with additional circuitry and are then decoded to produce the correct A, B, F and S signals. Therefore, only the M1, M2 and LOAD signals need to be generated external to the testability latches (normally from off chip). Table II defines the encoding for and operation modes of the TLATCHG configuration.
[Ref. 12:pp. 15-14, 15-15]

TABLE I
TLATCHU CONFIGURATION OPERATION

Required Inputs A B F S	Operation Mode
0 0 0 0	NORMAL
1 0 0 0 0 1 0 0	SHIFT*
0 0 1 0	FORCE
0 0 0 1 0 1 0 0	SAMPLE*
0 0 0 1 0 0 1 0 0 1 0 0	SWAP*

*Mode requires a sequence of non-overlapping strobes in the order shown.

TABLE II
TLATCHG CONFIGURATION OPERATION

Encoded Inputs M1 M2	Operation Mode	Decoded Outputs Relative to Clock Phases	
		phase_a	phase_b
0 0	SHIFT	A	B
1 0	FORCE ⁽¹⁾	F	B
0 1	SAMPLE	S	B
1 1	SWAP ⁽²⁾	S	-

⁽¹⁾LOAD signal disabled during phase_a of FORCE cycles.

⁽²⁾SWAP must be followed immediately by a FORCE cycle to override Latch D and advance the Latch D contents into Latch S2.

3. The TLATCHL configuration. It is similar to the TLATCHG configuration except that it uses its own local clock vice the global system clock to produce timing information. Use of this local clock allows this configuration to perform operations independently of the status of the global system clock. The clock signals phase_ta and phase_tb are derived from this local clock and provide properly timed control sequence orders for the A, B, F, and S control signals. Normally the local clock signal originates as an additional external input to the chip. The M1 and M2 control signals perform in the same manner as they do for the TLATCHG configuration. Table III defines the encoding for and operation modes of the TLATCHL configuration. [Ref. 12:pp. 15-10, 15-11]

As is discussed in Chapter 3, the TLATCHL configuration was chosen as the means of incorporating a scan path into the 16-bit correlator chip which was fabricated.

TABLE III
TLATCHL CONFIGURATION OPERATION

Encoded Inputs M1 M2		Operation Mode	Decoded Outputs Relative to Clock Phases phase_ta phase_tb	
0	0	SHIFT	A	B
1	0	FORCE ⁽¹⁾	F	B
0	1	SAMPLE	S	B
1	1	SWAP ⁽²⁾	S	-

⁽¹⁾ LOAD signal disabled during phase_ta of FORCE cycles.

⁽²⁾ SWAP must be followed immediately by a FORCE cycle to override Latch D and advance the Latch D contents into Latch S2.

III. DESIGN FOR TESTABILITY IMPLEMENTATION METHODOLOGY

This chapter discusses the methodology used with the Genesil Silicon Compiler to implement a chip incorporating DFT. The different menu features needed, used, and available within Genesil serve as the chapter subdivisions for presenting information on the different actions and multiple criteria considered during the production of a DFT chip design. Although the chapter was broken into subsections based on working with features within Genesil, it must be realized that chip design in Genesil involves a continuous interrelationship between all Genesil features available. Results obtained or decisions made during the progression of design steps while using one Genesil feature will carry over into the results obtained or approach taken while using another Genesil feature. Design in Genesil can be an iterative process involving multiple cycles of design changes due to information obtained from the different Genesil features. Specific information on all aspects of Genesil is provided in the documentation for the Genesil Silicon Compiler. Additionally, Reference 13 provides excellent information and a tutorial on the methodology for and makeup of a Genesil produced design.

To present a high level view of the chip as a whole, this chapter starts by presenting a functional description of the complete correlator chip design. The remainder of the chapter

concentrates on the specific reasoning which was used, the engineering design decisions which were made, and the steps which were taken to produce the chip design. The second section in this chapter discusses the operational and engineering design criteria which were established and the specific methodology steps used within Genesil to produce a chip which met these criteria. The third section emphasizes both the steps used and information gained from functional test simulation and timing analysis. The last section provides information on how Genesil's Automatic Test Generation feature was used both to produce a maximum fault coverage test vector set and to fault grade the test vectors produced during functional test simulation. Although placed last in the chapter, this section also provides further analysis on the process used to decide where to place and how to utilize the DFT technique of a scan path.

A. FUNCTIONAL DESCRIPTION

The chip which was fabricated is a 16-bit correlator. It performs a comparison between an incoming 16-bit word of data, which is placed into the data register, and a preloaded 16-bit word of data found in the reference register. The chip performs a bit by bit comparison between the two registers and produces a 5-bit binary number which indicates the number of bits, from zero to 16, that are positively correlated (matched) between the two registers. Additionally, a 16-bit mask register exists to enable or disable the correlation

process for a given set of bits in the data and reference registers. If the mask register has a specific bit set to a logic 1 the correlation results for corresponding bits in the data and reference registers are included in the correlation process. If the mask register has a specific bit set to a logic 0 the correlation results for the corresponding bits in the data and reference register are not included in the final result which indicates the total number of bits that matched. The data, reference, and mask registers are all provided with a means to be selectively loaded in either a serial or parallel manner. The final correlator chip design is partitioned into five main sections: input registers, XNOR register, combiners/testability latches, adder and output. Figure 3.1 is a block diagram showing the relationships and main signals of these sections.

1. Input Registers

The input section of the chip consists of three identically designed input register general modules: **data_in** (the data register general module), **ref_in** (the reference register general module) and **mask_in** (the mask register general module). Each of these input register general modules holds a 16-bit word to be used during the correlation process. These 16-bit words can be controllably loaded in either a serial manner via the **SERIAL_IN** input pin and **serial_in** signal or in a parallel manner using the **IN_PADS[15:0]** input pins and **par[15:0]** signals. The value of the **sp_con** signal, as input

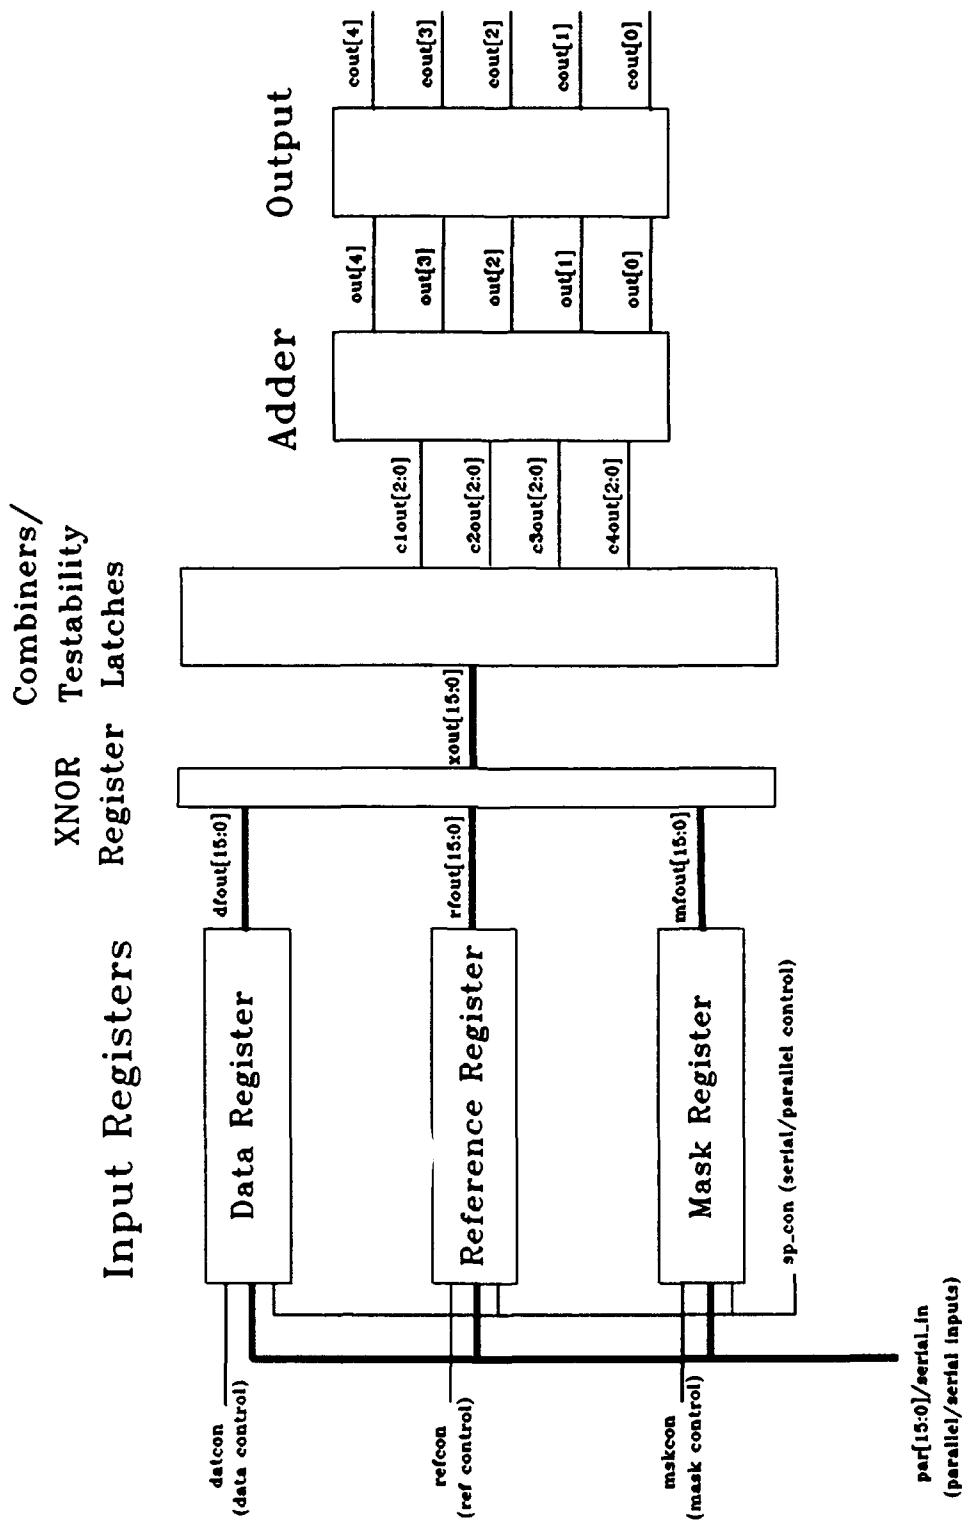

Figure 3.1 Correlator Chip Block Diagram

to the **SPCON** input pin, determines which load method is used. If **sp_con** is a logic 1 the 16-bit words are loaded in a serial manner. If **sp_con** is a logic 0 the 16-bit words are loaded in a parallel manner. A load control signal (**datcon** for the **data_in** general module, **refcon** for the **ref_in** general module, and **mskcon** for the **mask_in** general module) is used to control whether an input register general module is allowed to load data which is present at the **SERIAL_IN** or **IN_PADS[15:0]** pins or whether loading is disabled for a particular input register general module. As a result, the three input register general modules can controllably load either the same data all at once or individually load different data one at a time via manipulation of their load control signals.

Each input register general module consists of two serially connected 8-bit shift register modules, to hold the 16-bit words, and a control block. The shift register modules (**data1** and **data2** for the **data_in** general module, **ref1** and **ref2** for the reference general module, and **mask1** and **mask2** for the mask general module) are formed from eight D flip-flop/multiplexer combinations. During serial loads the input for each D flip-flop is the output from the previous D flip-flop/multiplexer stage. The output line for the MSB of the first shift register module is connected to the serial input line of the multiplexer for the LSB of the second shift register module. Thus the two shift register modules are effectively connected in a serial manner to form a 16-bit shift register. For

parallel loads, the multiplexers get the input values to pass to the D flip-flops via the `par[15:0]` signal lines. The `sp_con` signal controls the multiplexers to determine whether they pass values to the D flip-flops from their serial or parallel load lines. The control block for each input register general module consists of a simple two-input AND gate which has `phase_b` of the global system clock as one input, the appropriate load control signal as the second input, and which produces the clock signal for the D flip-flops of the shift register modules as its output. Therefore, making the load control signals a logic 1 allows passage of the `phase_b` clock signal so that the D flip-flops can be loaded with new values. A load control signal set to logic 0 inhibits the clock signal to the D flip-flops thus causing them to retain their present values regardless of any changes to the values present at the chip's serial or parallel input load pins. Figure 3.2 illustrates a 1-bit wide slice from an input register general module.

2. XNOR Register

The XNOR register is a random logic module, labeled `xnorreg`, consisting of 16 two-input XNOR gate, two-input AND gate combinations. One combination is used for each of the 16 bit positions for the correlation process. Figure 3.3 depicts a 1-bit wide slice of the XNOR register module. The two inputs to the XNOR gates are the outputs from the D flip-flops of the data and reference registers. The XNOR gate produces

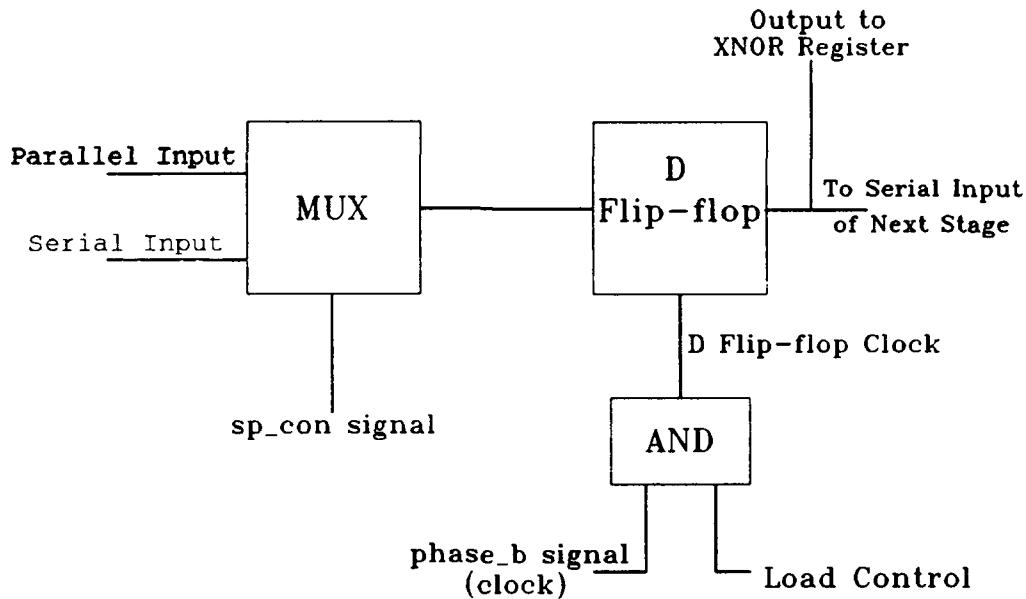

Figure 3.2 1-Bit Wide Slice of an Input Register

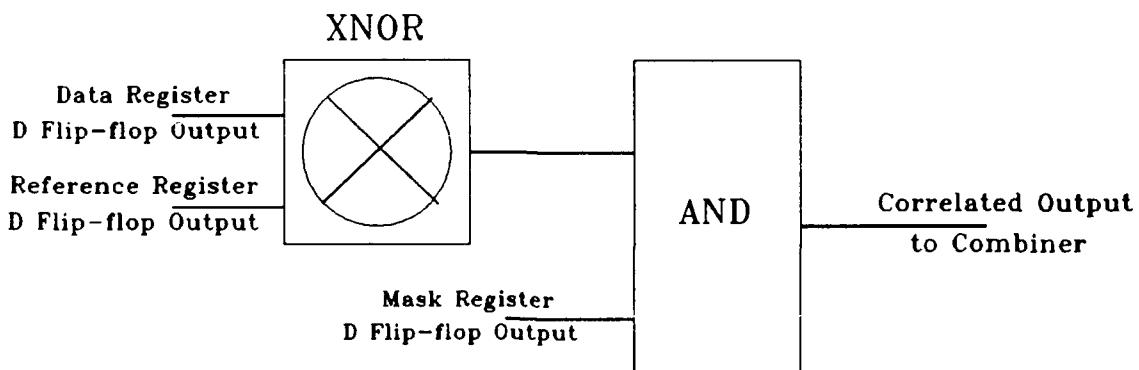

Figure 3.3 1-Bit Wide Slice of the XNOR Register

an output which is a logic 1 if these values are positively correlated (match) and a logic 0 if they are different. Thus it in effect compares each corresponding bit position in the data and reference registers. The output of the XNOR gate along with the output of the D flip-flop from the corresponding bit position of the mask register serve as inputs to the AND gate. Therefore, the mask register bits determine whether positively correlated results obtained from the data and reference registers are passed onwards to be counted or are blocked from being considered. A logic 1 in a mask register bit position produces a logic 1 output from the XNOR register in that bit if the data and reference register words match and a logic 0 if they do not. A logic 0 in a mask register bit position causes the XNOR register to output a logic 0 for that bit position regardless of how the data and reference register bits correlate. It thus causes that bit position to become masked from inclusion in the final chip output which indicates the number of positively correlated bits.

3. Combiners/Testability Latches

The purpose of the two combiners, **combiner1** and **combiner2**, is to collectively reduce the output of the XNOR register to four 3-bit binary numbers. Each 3-bit binary number is the summed total of positively correlated, nonmasked bits from a 4-bit wide slice of the data and reference registers as output by the XNOR register. Figure 3.4 shows the logic gate representation of how one 4-bit wide slice of

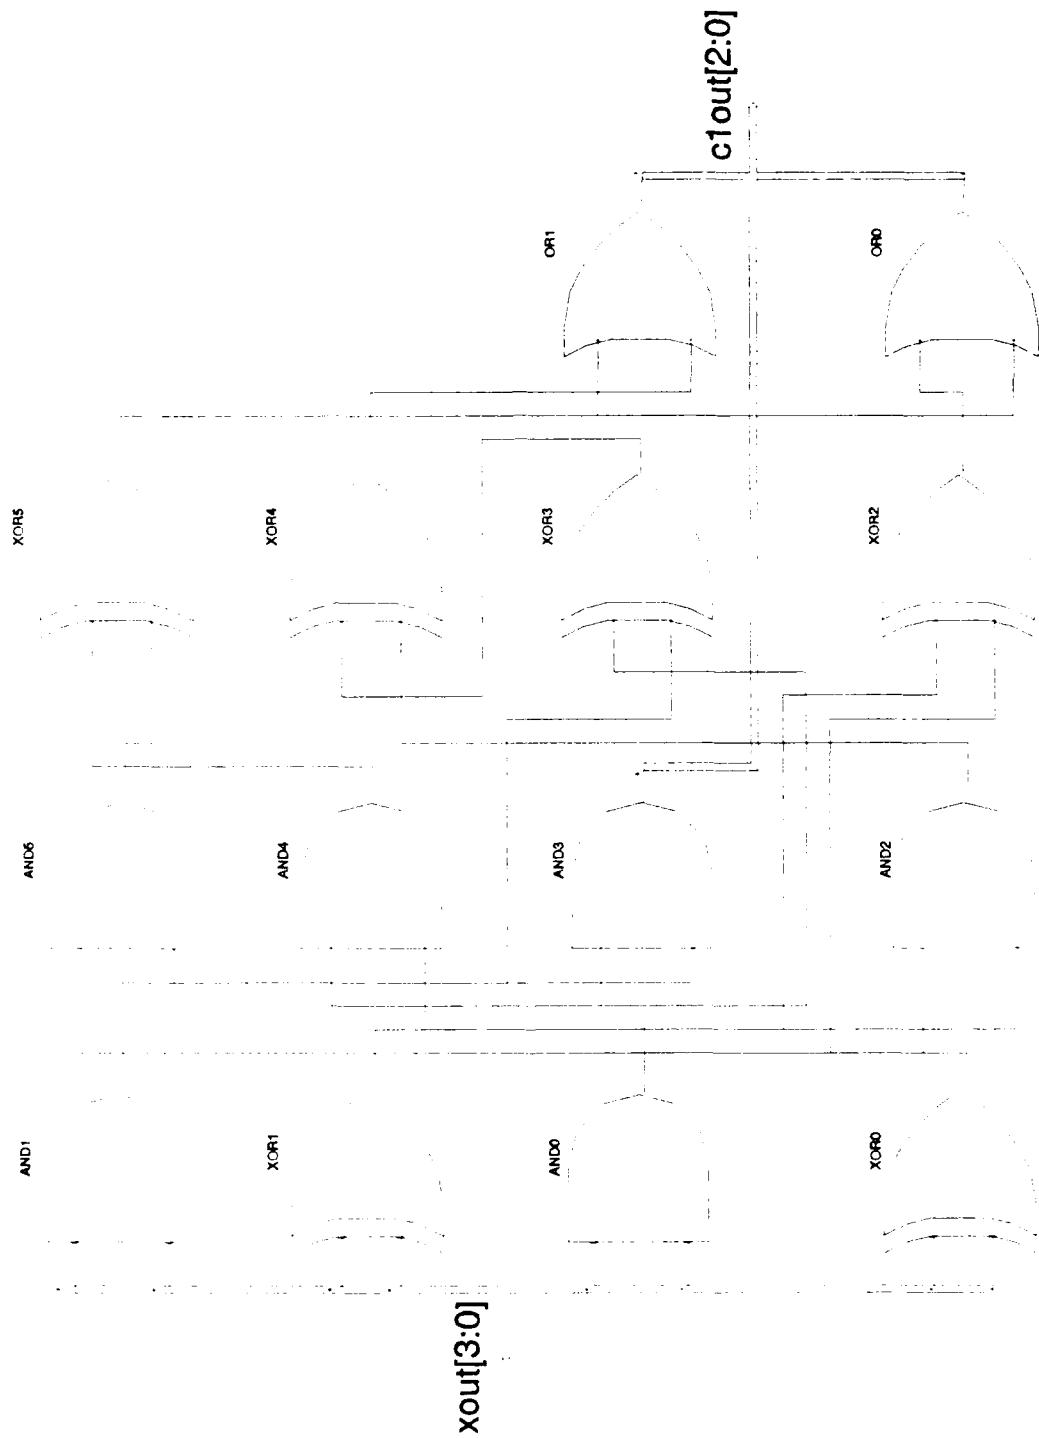

Figure 3.4 Combiner Circuit 4-bit Wide Slice

results from the XNOR register output is summed to produce a 3-bit binary number representing the total of positively correlated bits. To incorporate design for testability features into the chip, a scan path consisting of serially connected testability latches was placed between the gates of the combioer function as indicated by the dashed line of Figure 3.5. This dashed line represents the demarcation between the gates, for a given 4-bit slice of the combiner function, which belong to combiner1 and those found in combiner2. A discussion on why the scan path was placed here is provided in the last section of this chapter.

The testability latches themselves are located in the **tLatch32** module which is formed from two 16-bit testability latches (the maximum random logic testability latch size allowed in Genesil) **tLatch0** and **tLatch1**. The testability latches are operationally controlled via the control signals **m1**, **m2**, and **load** which originate from the **M1**, **M2**, and **LOAD** input pins respectively. Additionally, data can be scanned into and out of the chip through the scan path testability latches using the **testin** and **testout** signals from the **TESTIN** input pin and **SHIFTOUT** output pins. The clocking needed for the different operations of the testability latches is provided by the **phase_ta** and **phase_tb** clock signals derived from the clock signal input to the **CLOCK2** input pin.

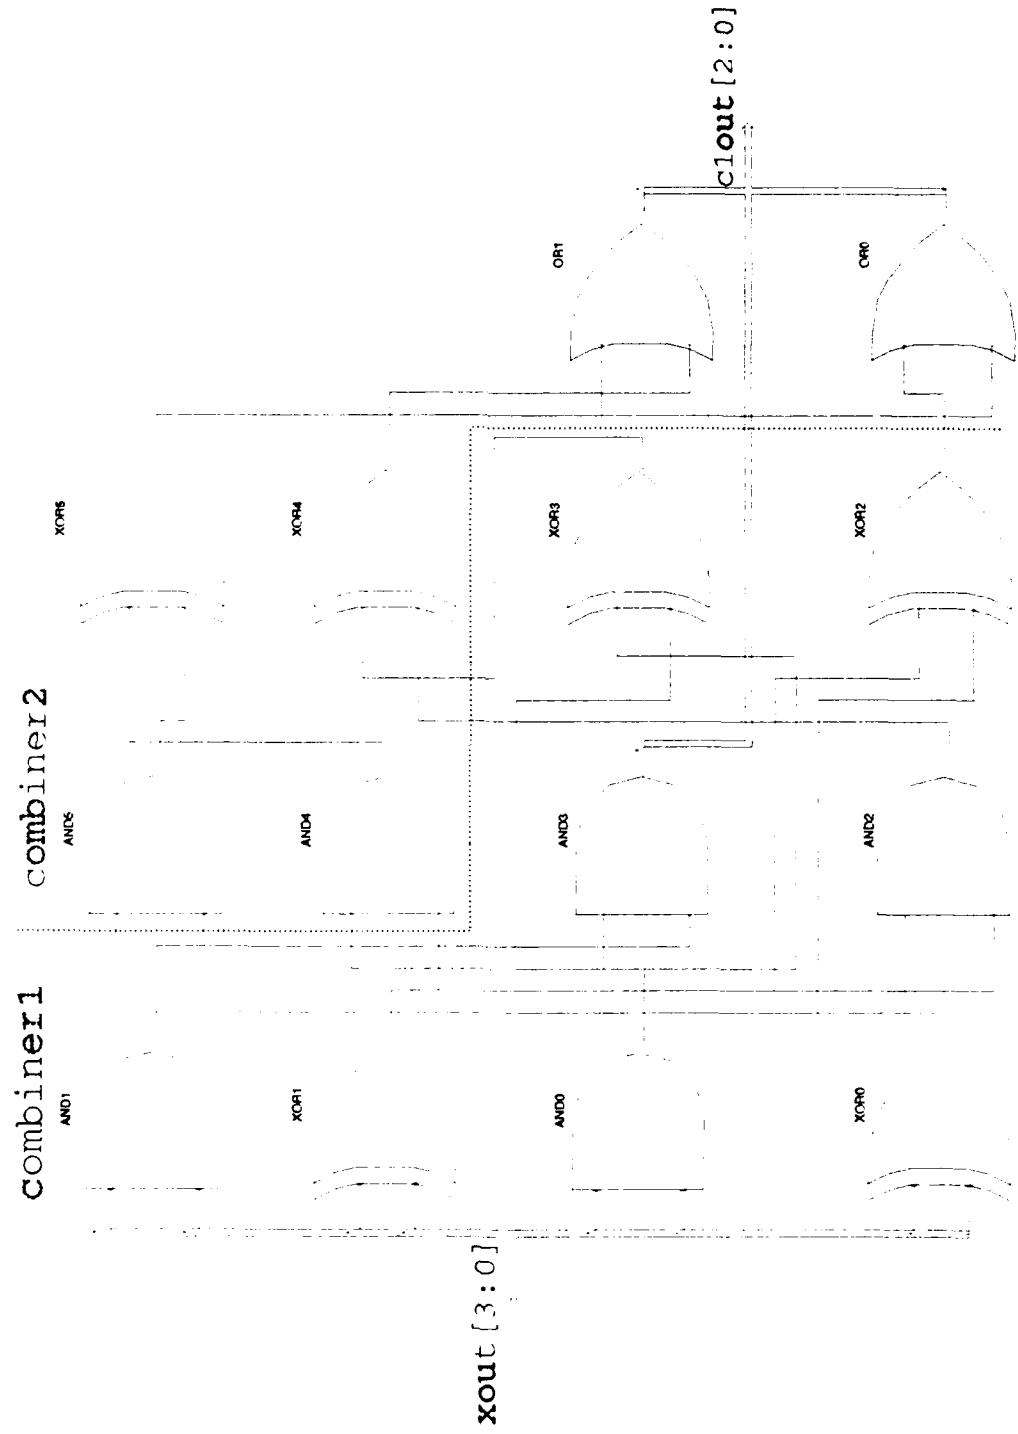

Figure 3.5 Testability Latch Placement

4. Adder

The purpose of the **adder** section is to take the four sets of 3-bit binary numbers produced as an output of the combiner function and add them together to produce a 5-bit binary number which represents the sum total of all positively correlated, nonmasked bits between the 16-bit words in the data and reference registers. The adder module consists of three adders. There are two 3-bit adders, **ADDER0** and **ADDER1**, which each take two 3-bit binary numbers output from the combiner function and add them to produce a single 4-bit number. The third adder, **ADDER2**, takes the two 4-bit numbers produced by **ADDER0** and **ADDER1**, adds them together, and produces the 5-bit binary number result on the signal lines **out[4:0]**. Figure 3.6 shows the configuration of the adder module.

5. Output

The **output** module is included on the correlator chip as a means whereby the output results of the correlation process can be controllably turned on or off. This section consists of five two-input AND gates as shown in Figure 3.7. Each AND gate has as one of its inputs a single bit from the final binary number result produced by the adder section and as its other input the control signal **output** which originates from the **OUTCON** input pin of the chip. The outputs from the AND gates form the final output signals **cout[4:0]** which are sent out of the chip via the output pins **OUT_PADS[4:0]**. Thus,

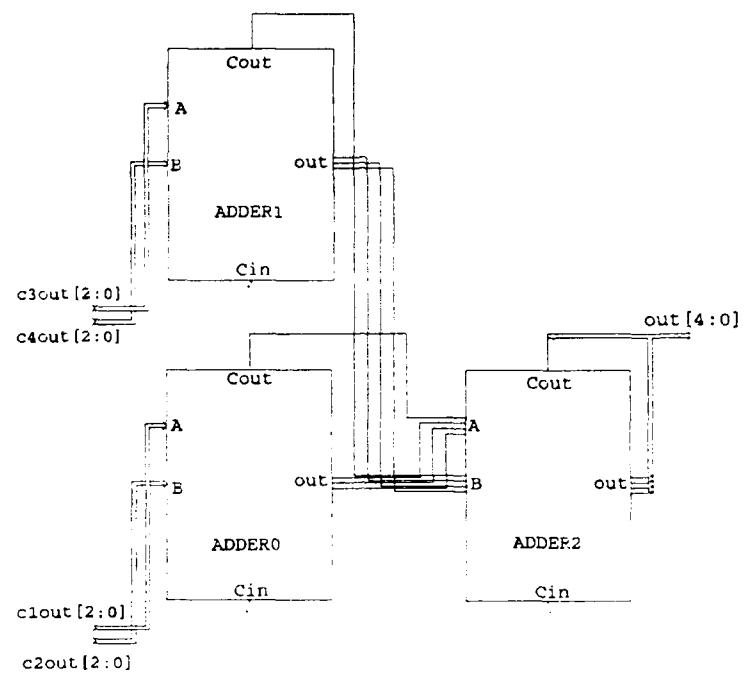

Figure 3.6 Adder Section Configuration

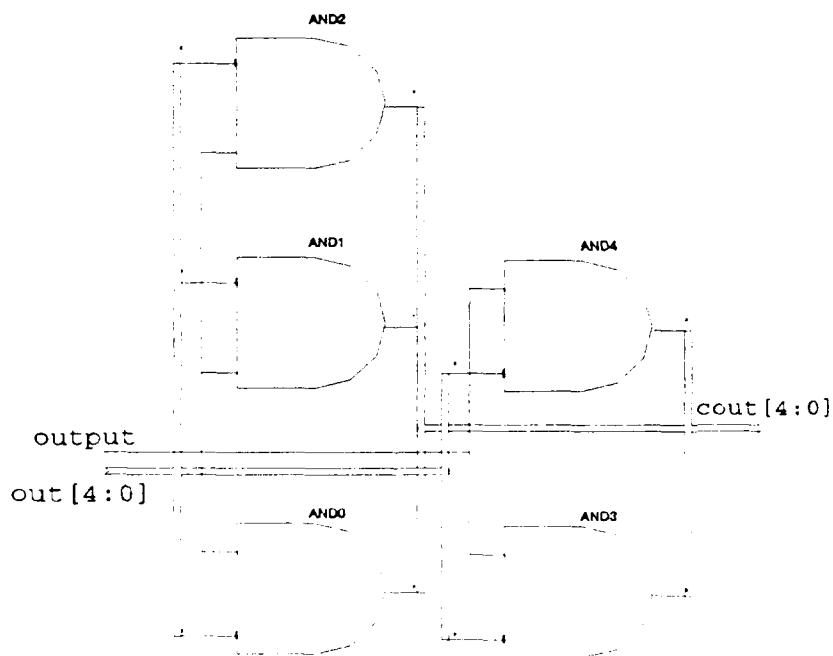

Figure 3.7 Output Module Configuration

the control signal named output can either activate the chip allowing results to be presented to the outside world or inhibit the presentation of these results.

B. DESIGN CRITERIA, DECISIONS AND TECHNIQUES

The final 16-bit correlator chip design produced was affected by both specific engineering design and operational criteria and by the procedural steps necessary for designing a chip in Genesil. Since Genesil produces chips by utilizing a library of already designed objects (Genesil blocks), the chip designer must accept the limitations of producing designs done at the gate level or above instead of working at the transistor level. Therefore, the cost of working in Genesil is less ability to optimize the design in terms of performance and chip size. In contrast, using Genesil provides benefits related to areas such as reduced design time, a lower level of required designer knowledge, easy to use simulation capabilities and a fast means of determining fault coverage levels.

For comparison purposes, two 16-bit correlator chips were designed in Genesil. **BASIC_CHIP** is the 16-bit correlator design discussed in the functional description without any DFT technique included. **DFT_CHIP** is the same design but with the addition of testability latches to form a scan path as discussed in the functional description. Within the limitations of Genesil, the following set of criteria was established for the DFT_CHIP:

1. Functionally, the DFT_CHIP should produce the same correlation results for a given set of bits in the data, reference, and mask registers as does the BASIC_CHIP.
2. The only difference between the DFT_CHIP and the BASIC_CHIP should be the addition of testability latches, along with pins for the supporting control, clock, and I/O signals, to form a scan path.
3. The design area size for the DFT_CHIP should be minimized to the greatest extent possible to lower fabrication costs.
4. The fabrication line and feature size chosen for usage in Genesil should be compatible with those possible for chip fabrication via MOSIS.
5. There should be a maximum of 40 pins for the DFT_CHIP to allow it to be accommodated in the test jig available for use with the commercial tester.
6. The testability latches used should be of the TLATCHL type to gain the advantages of using a local clock to perform operations in the scan path.
7. Fault coverage for the chip should be maximized through the choice of where to place the scan path to increase observability and controllability.
8. The DFT_CHIP should be designed to utilize the highest clock frequencies possible within the limitations of the other criteria.

As can be seen, these criteria are divided between those related to fabrication requirements and those related to desired performance or operational characteristics.

The overriding criteria for the fabrication requirements became the need to layout a chip design that was both small enough and oriented properly to fit within a maximum design area size of 4.6mm wide by 6.8mm high. This size limitation originated from the need to keep the fabrication cost for the chip within a reasonable limit. The size of 4.6mm by 6.8mm is the largest which could be used for fabrication via MOSIS

within the budget allocated for the chip. The criterion emphasized for performance was maximizing the fault coverage possible for the chip. This necessitated intelligent placement of the scan path to enhance observability and controllability. Information on how this was accomplished is located in the subsection of this chapter titled Automatic Test Generation and Fault Coverage.

1. Design Decisions and Techniques to Minimize Size

The design steps for the DFT_CHIP followed the normal sequence used in Genesil. First, blocks were chosen from the available library and combined to form modules. Based on utilizing individual gates for the designs of the input registers, XNOR register, combiner and output sections of the chip, Genesil **random logic blocks** were used to accomplish this. Netlisting was used to specify the signal interconnections between the blocks. The objects making up the input registers were further netlisted and then floorplanned together to form larger general modules. Note that at this point the input register general modules consisted of a single 16-bit shift register and the control block. These actions resulted in the following modules and general modules being created: data_in, mask_in, ref_in, xnorreg, combiner1, combiner2, tlatch32, adder and output. Next, modules and general modules were placed into the chip and the **independent blocks** (pads) for the input, output, clock, and power supply pins were added. The chip as a whole was then floorplanned.

Finally, the chip was compiled using the VTI-CN20A 2.0um n-well CMOS process from VLSI Technology, Inc. as the choice from among the Genesil supported fabrication lines. To determine the size of the chip designed, a route plot as shown in Figure 3.8 was produced.

Since the first design attempt produced a chip of size 5.902mm by 8.276mm, chip size reduction was mandated. Most of the work done to reduce chip size involved changes to the way the chip was floorplanned. Floorplanning in Genesil consists of three categories: placement, pinout and fusion. **Placement** determines the manner and orientation in which objects are physically located next to each other. For the initial design attempt the Genesil **AUTO_PLACEMENT** (automatic placement) feature, **AR_PLACE** option was utilized. This feature and option performs placement based on an attractive repulsive algorithm which orients objects with many common signals next to each other irrespective of their sizes [Ref. 14:p. 3-7]. Figure 3.9 shows the placement configuration which resulted from using automatic placement. To optimize the size in the subsequent design attempts, manual vice automatic placement of the objects was used. Manual placement allows a designer to specify exactly where items should be located in relationship to each other. For the **DFT_CHIP** this allowed the input register general modules to be oriented along the height axis, at right angles to the other modules, to attempt to form a rectangle smaller than the 4.6mm by 6.8mm space allotted.

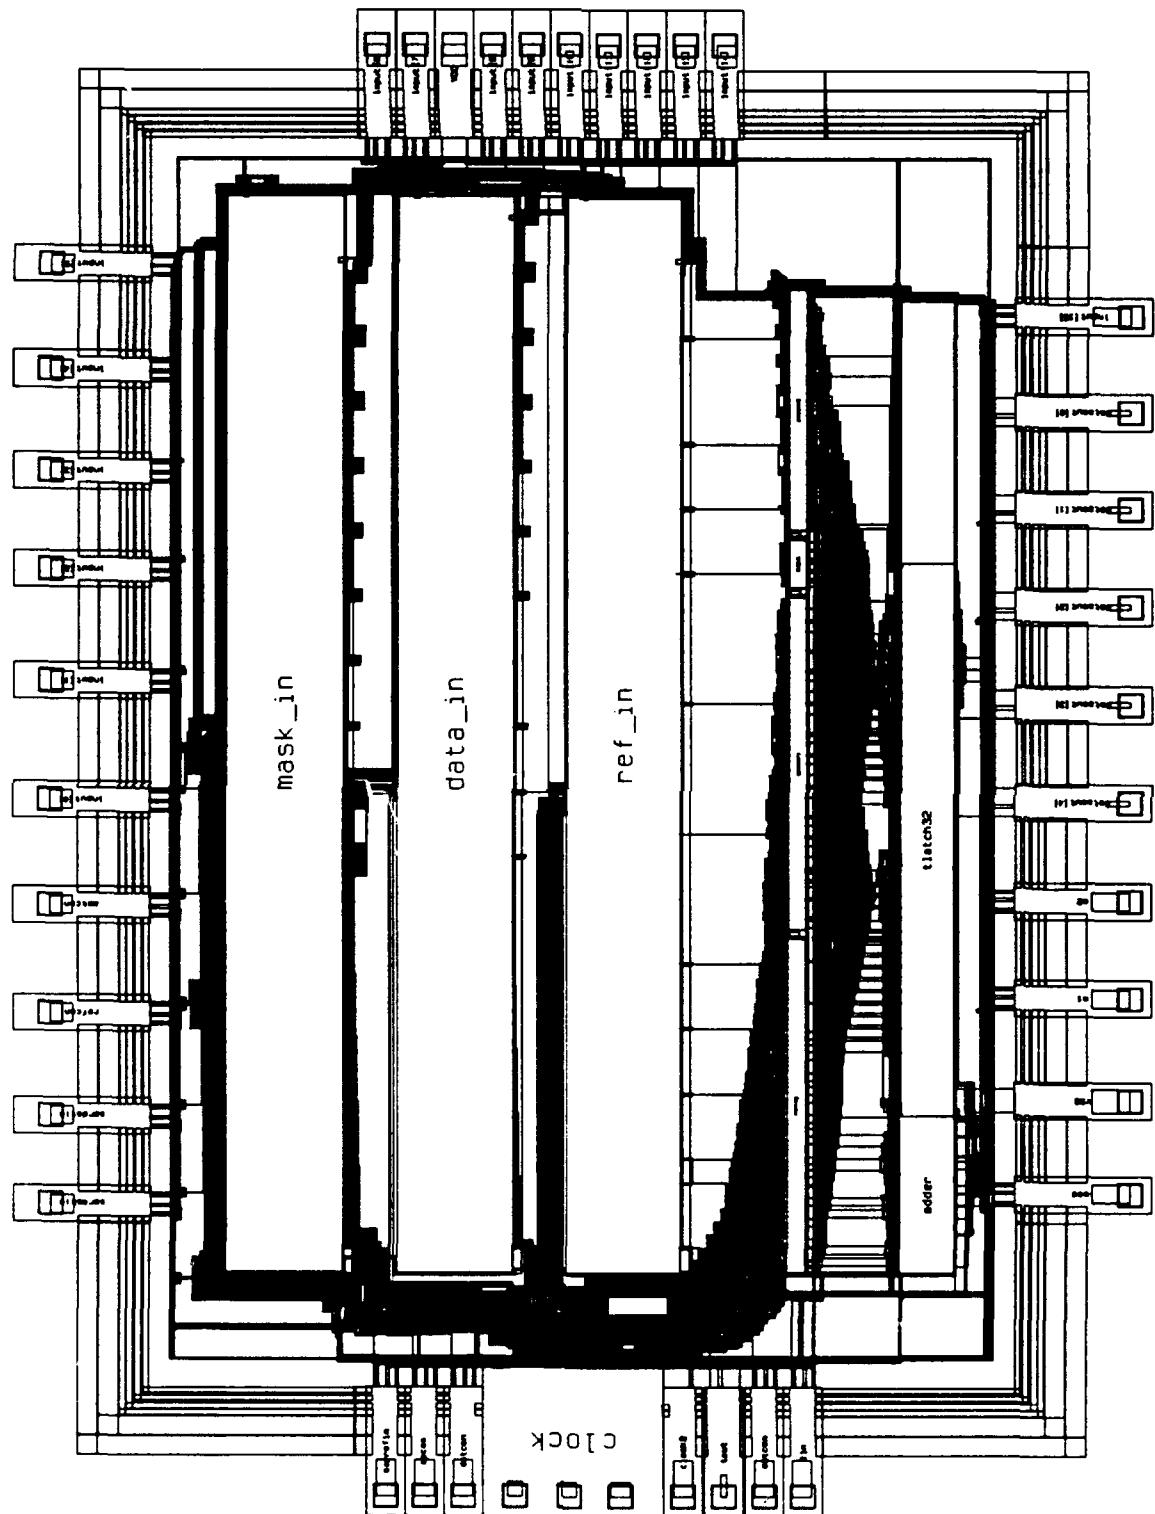

Figure 3.8 Route Plot for First Design Attempt

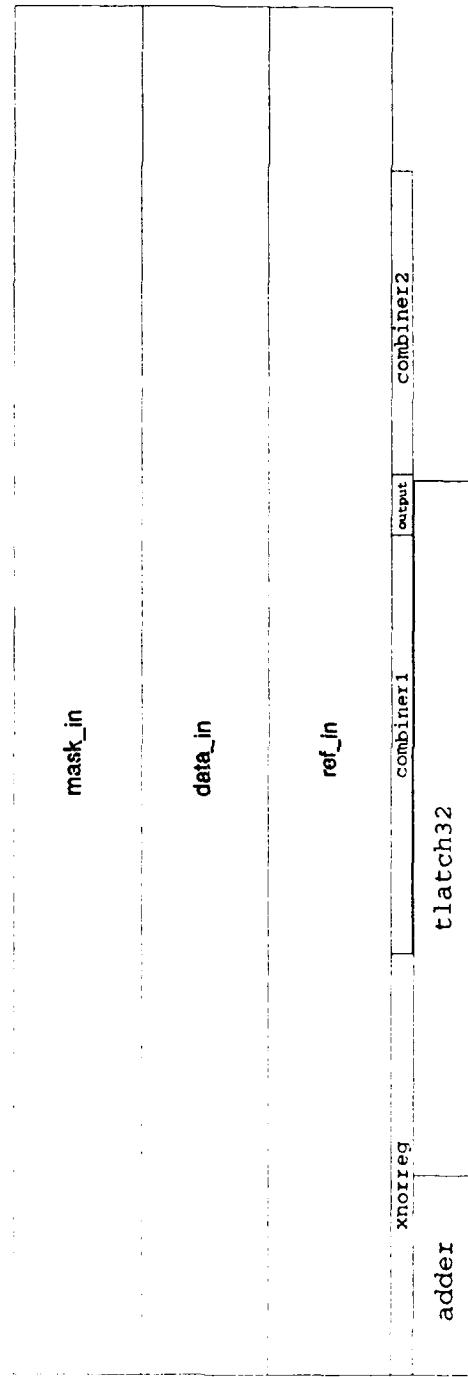

Figure 3.9 Placement Configuration from using
AUTO_PLACEMENT Feature, AR_PLACE Option

Figure 3.10 shows the modified placement configuration which resulted from the use of manual placement.

Manual placement still did not solve the size problem. The chip produced was almost within the width tolerance of 4.6mm but was elongated along the height axis due to the thin, long nature of the input registers. To solve this problem the input registers were redesigned. The 16-bit shift register sections were broken into the two 8-bit shift register sections discussed in the functional description. The input register general modules were then refloorplanned, using manual placement, to place the two 8-bit shift register sections side-by-side. The resulting input register general modules were approximately half as elongated and twice as wide as the original configuration. Figure 3.11 shows the placement configuration of the data_in input register prior to the change. Figure 3.12 (shown at a larger scale) shows the results after the change. This modification turned out to be the single largest size reducing decision made for the chip. Not only did it reduce the elongation of the height axis of the chip but it also caused less nonoccupied/nonutilized space to be present within the chip design.

To further reduce the size dimensions, the other two aspects of floorplanning were considered. First, the floorplanning **pinout** feature was utilized. Within general modules the pinout feature allows choices to be made as to which side of a general module (north, east, south, or west) connectors

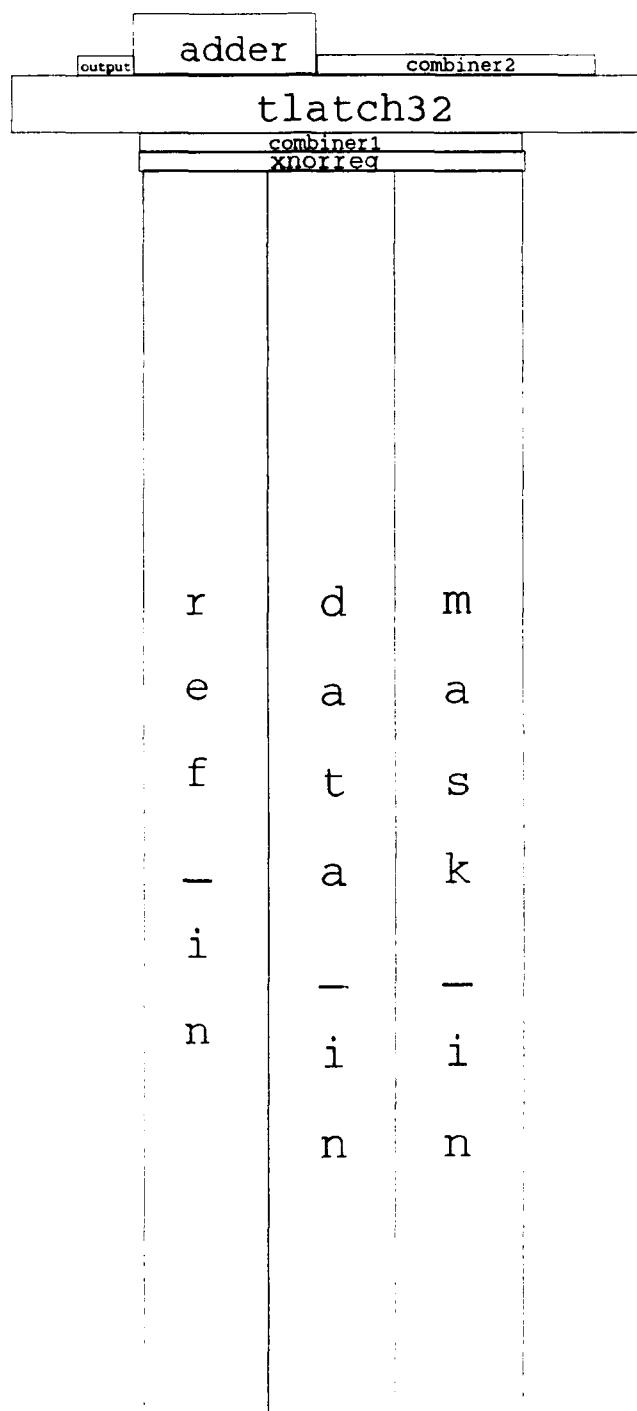

Figure 3.10 Placement Configuration from using
Manual Placement

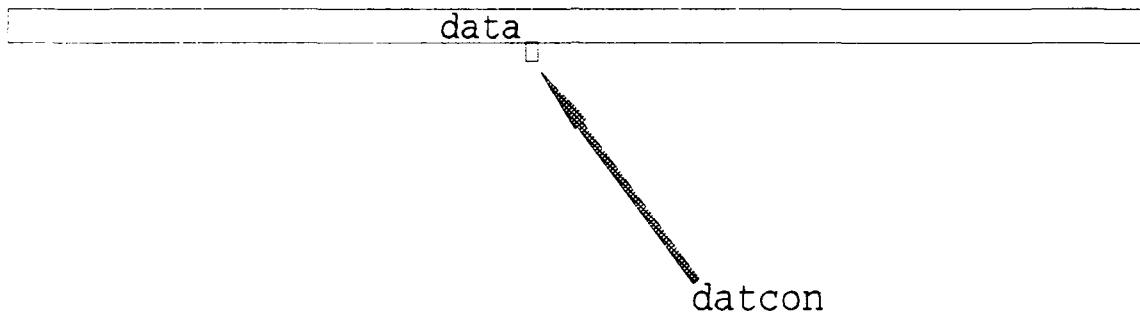

Figure 3.11 Input Register Placement for Single 16-bit Shift Register Section

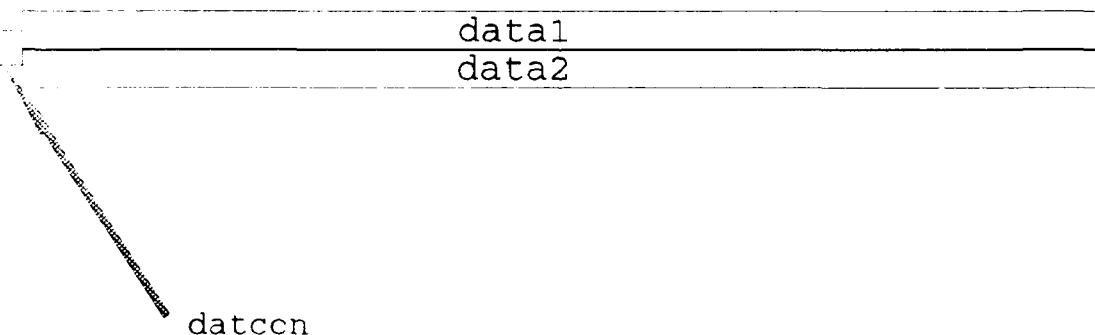

Figure 3.12 Input Register Placement for Two 8-bit Shift Register Sections

for signals going to or from the general module will be placed. By considering how general modules have been placed within the chip a designer can optimize the routing direction of signals between general modules and other chip objects. Connectors for signals in the general modules should be placed on the side of the general module closest to the chip objects which share the signals. Figure 3.13 is an example of the pinout form used to specify connector edge locations for a general module. At chip level pinout determines the pad placement locations for signals which exist external to the chip. By placing pads for specific signals as close as possible to the objects using these signals wire lengths and routing complexity within the chip can be decreased.

The last feature of floorplanning utilized to reduce the chip size was the **fusion** feature. Fusion determines the assignment of routing channels which affect wire routing within the floorplan of the chip [Ref. 15:p. 7.5]. Routing channels are formed through the fusion of two objects, the fusion of one object to a previously defined fusion region, or the fusion together of two previously defined fusion regions [Ref. 15:p. 7.5]. Chip size can be minimized by performing fusion in a sequence that fuses together items whose adjacent boundaries are the same length [Ref. 15:p. 7.5]. Genesil offers the features of both **AUTO_FUSE** (automatic fusion) and **FUSE** (manual fusion). **AUTO_FUSE** automatically fuses together all items not already fused but does not necessarily produce

the most efficient floorplan [Ref. 15:p. 7.17]. To help reduce the chip size a change was made from using automatic fusion on the first design attempt to using manual fusion on subsequent design attempts. The ability to reduce chip size through intelligent manual fusion decisions was validated during this process. However, if manual fusion is going to be used it must be done carefully since it was determined that unwise fusion order choices can have highly adverse effects on overall chip size.

Upon completion of all the changes discussed concerning floorplanning the chip size had been reduced to 4.743mm by 6.727mm. To achieve the additional small reduction in size needed for the width axis two additional design decisions were considered. First, Genesil provides the choice of using either TTL or CMOS drivers for output pads. Output pads using CMOS drivers are larger than those using TTL drivers and will increase the size of the pad ring surrounding the core of the chip [Ref. 16:p. 5-4]. Secondly, Genesil provides two options for electro-static discharge (ESD) protection for input pads. ESD circuitry is used to prevent the damaging buildup of large static voltage potentials at input pads, which is common to CMOS chips, by providing a low-impedance discharge path through diodes to either the VDD (power) and or the VSS (ground) supplies [Ref. 16:p. 5-3]. Genesil provides two ESD protection options when specifying the input pad configuration. **NP-PROTECT** uses protection diodes connected to both the

VDD and VSS supplies but produces pads larger in size than N-PROTECT which provides only a protection diode to the VSS supply [Ref. 16:p. 5-3]. The initial chip design utilized TTL output drivers and the NP-PROTECT option. To achieve the remaining size reduction needed, the final DFT_CHIP design sacrificed some degree of protection by using only the N-PROTECT option. This choice reduced the final design to a size of 4.550mm by 6.627mm. Figure 3.14 is a route plot for the DFT_CHIP which shows the final configuration results obtained for the overall size minimization process.

2. Additional Design Decisions and Techniques

The remaining design decisions made for the DFT_CHIP can be split into those related to scan path operations and those related to pad specifications. Based on the criteria of desiring scan path operations to be able to proceed independently of the global system clock, the TLATCHL testability latch configuration was chosen to form the elements of the scan path. Only this Testability Latch configuration, from among those available in Genesil, provides the ability to work with a local clock for scan path operations. The criteria requirement itself was established to enhance chip capabilities by providing both a method to perform in-system testing of an operating chip and to allow operation of the scan path a different clock rate from that of the rest of the system. In-system testing for a chip involves checking its operating condition without removing it from its physical working

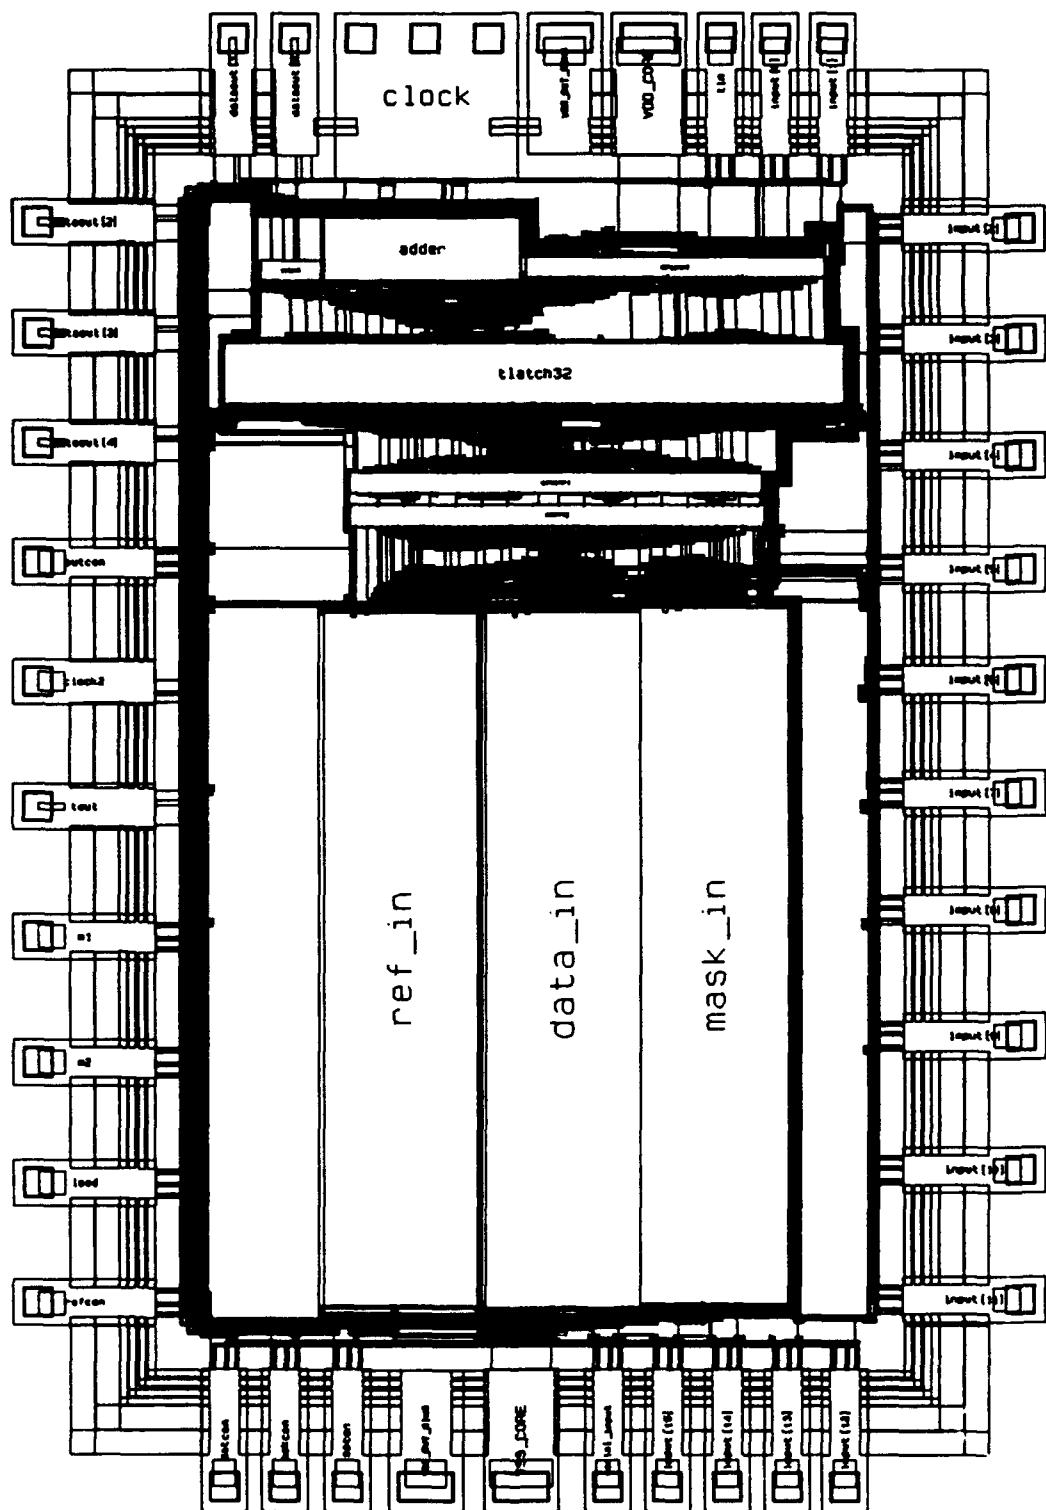

Figure 3.14 DFT_CHIP Final Configuration Route Plot

environment. This could be done in the DFT_CHIP by halting normal chip operations through either disabling the load control signals (datcon, mskcon and refcon) to the input registers or through disabling the testability latch load signal. The chip would then be in a test mode where the local scan path clock scans test vectors into or out of the chip to check its operation. The use of the TLATCHL configuration was also chosen to attempt to make possible the use of a clock for scan path operations that both runs at a higher speed than the global system clock and that can continue scan path operations during periods when the global system clock is not operating. These features would help speed the rate at which test vectors or test results could be scanned into or out of the chip and also would enhance the chip's in-system testing capabilities.

Design choices for the pad specifications were made to enhance operational performance while still being conservative enough to help insure that the fabricated chip would operate satisfactorily. First, pads for power supplies had to be provided to the chip. Genesil produces designs which require power for two separate regions: the chip core and the pad ring [Ref. 16:p. 5-59]. Options exist in Genesil to provide this power through either separate VDD and VSS pad pairs for each region or through a single combined pad pair for both regions. Except for small pad-limited designs, the combined option is not recommended since it does not provide any isolation from noise which might be generated by the output pad drivers

[Ref. 16:p. 5-61]. Therefore, the conservative choice of using separate VDD/VSS pad pairs for the ring and core power supplies was made for the DFT_CHIP.

Next, the specifications were made for the clock pads used by the input signals for the global system clock and the scan path local clock. Genesil clock pads convert a single external clock signal into internal two-phase non-overlapping clock pair signals required to operate genesil blocks [Ref. 16:p. 5-15]. The DFT_CHIP uses the clock pad option of **NO_DIVIDE** which provides internal clock signals at the same frequency as the external clock signal. Clock pads have their own power source requirements which depend on the loading placed on them. The primary global system clock must be provided with its own power pads (VDD and VSS) which are isolated from the ring power supplied to the other ring pads [Ref. 16:p. 5-25]. To accomplish this requirement the **LOCAL_ISOLATED** option was chosen for the primary global system clock pad. This choice produced a clock pad with its own VDD and VSS inputs attached. For additional clock pads in a multiple clock design the requirement for isolated power is dependant upon the degree of loading placed on the clock signals. A lightly loaded clock ($\leq 20\text{pF}$) can utilize power distributed by the ring power pads vice needing its own power supplies [Ref. 16:p. 5-26]. Since the local clock for the scan path testability latches met this requirement, ring power was used vice choosing isolated power. Note that the maximum

operating frequency to be used for the clocks is not chosen in the pad specification but rather is done during the netlisting process for the clock signals.

Decisions concerning the input pads were made next. The decision on ESD was described previously in the section on minimizing chip size. The other design decision for the input pads was to choose whether external signals would be latched or passed completely untouched from outside to inside the chip. For the DFT_CHIP, Genesil's Direct option, which provides a transparent latch at the input pad, was chosen. A latch configuration was chosen to ensure that there would be at least a half clock cycle during which unchanging input data could propagate to and be placed into the input registers. Input data is sampled and passed during phase_b of the latch clock signal and is held during phase_a [Ref. 16:p. 5-39]. After chip fabrication, a major design error was discovered concerning the clock signal used to control the latch for the scan path input pad. Instead of specifying sampling during phase_tb of the local scan path clock, the genesil default of phase_a of the global system clock was accepted as the controlling clock signal. The result of this design oversight is the negation of the ability to conduct scan-in operations for the scan path at either a rate faster then the global system clock or when the global system clock is not operating. Since this ability was part of the reason for choosing the TLATCHL type Testability Latches, this error was quite costly

in terms of available chip operational performance characteristics.

Lastly, decisions were made concerning the output pads. Output pads also have options concerning the presence or absence of latches. Again a transparent latch option was chosen to help ensure that the final results presented off chip would be stable for at least half a clock cycle. The transparent latch for output pads samples values during phase_a of its controlling clock and holds values during phase_b [Ref. 16:p. 5-39]. The controlling clock signals were correctly specified for the output pads. The output pads for the correlated results have their latches controlled via the global system clock. The scan path output pad latch uses the local scan path clock like it should thus allowing scan-out operations to proceed either at a faster rate then that of the global system clock or during periods that the global system clock is not operating. Finally, Genesil offers options on the drivespeed available for the output pads. The choice which can be made is dependant upon the number of VDD/VSS pairs present to provide ring power. A single pair as in the DFT_CHIP can drive six output pads at very high speed, 12 pads at high speed, 20 pads at low speed, or 40 pads at very low speed [Ref. 16:p. 5-37]. Since only six output pads exist for the DFT_CHIP, the very high speed **DRVSPED3** option was chosen.

C. SIMULATION AND TIMING ANALYSIS

Genesil's ability to perform simulation and timing analysis provides a convenient means to evaluate and analyze chip performance and functionality characteristics during the design process. Simulation and timing analysis are independent operations within Genesil's working environment. Both of them can and should be used during the entire design process for a chip. By performing analysis on individual modules before combining them into a chip design, timing or logic functionality errors can be easily debugged. Upon completion of a chip design, simulation and timing analysis provide a final verification that the design performs as desired.

1. Simulation

Simulation within Genesil is the process by which a chip design is evaluated to verify that both the implemented design and the physical layout generated from that design function as intended. Through the simulation process, outputs can be checked against a given set or sequence of inputs to verify that the design is logically correct. Genesil performs simulation using either a functional model or a switch-level model.

Simulation done using a functional (GFL) model is a technology and layout independent process. GFL simulation utilizes gate-level, zero-delay models of objects within the design [Ref. 17:p. 2-4]. Technology and layout independence is achieved by considering only the circuit functionality

characteristics and changes in input signals rather than looking at the actual delay times found within a circuit design [Ref. 17:p. 1-2]. GFL simulation uses a demand-evaluation algorithm which simulates only the minimum logic necessary to check for correct results [Ref. 17:p. 2-1]. Only block definitions and netlisting need to be accomplished prior to running a GFL simulation test.

In contrast, switch-level (GSL) model simulation is designed to verify functionality at a switch level once a particular technology is specified and the object layout is completed via use of the floorplanning and compilation processes [Ref. 17:p. 2-2]. GSL simulation uses an event-driven algorithm which forces any changes caused by an event to propagate through the design based on detailed timing information obtained from the Genesil Timing Analyzer for the particular technology and layout chosen [Ref. 17:p. 2-2]. GSL simulation is normally used only as a final design verification step during the design process.

Simulation operations in Genesil can be done in either a manual interactive mode or in an automatic control mode. The manual mode requires that the user specify each input, manually advance time via cycling the clocking signals, and individually verify each output. The automatic control mode allows simulation to proceed without user interaction by either operating on a set of test vectors which provide input signals and expected output signals or by using Genesil

simulation routines called **check functions**. The automatic control mode both runs faster than the manual mode and if test vectors are used can provide error messages to indicate differences between actual and expected output results [Ref. 17:p. 1-3].

Check functions in Genesil provide an automated approach to both simulate circuit operation and to generate test vector sets. Check functions consist of user defined simulation routines written in a proprietary Genesil language called **GENIE**. The GENIE language provides basic commands which can accomplish all the needed operations to perform simulation on an object. Reference 17 Appendix B provides specifications for the GENIE commands which can be used during simulation. In the manual interactive mode these commands are issued one at a time. By combining these basic commands into a check function routine, a complete simulation task can proceed by using only the check function name as a command. High level check functions can also be written which call lower level check functions and individual GENIE commands. This allows complete simulation procedures to be written for use in a batch type mode.

If check functions and GENIE commands are used in conjunction with the **traceobj** command, test vectors can be produced from simulation runs. The **traceobj** command causes all inputs and outputs obtained from the simulation run to be captured in a **MASM** test vector file. The MASM test vector

file format contains a list of all the inputs presented and the outputs obtained at each timepoint during the simulation. This MASM format is the same as that used by the Automatic Test Generation process. Therefore, test vectors produced via the simulation process using the traceobj command can be fault graded in the Automatic Test Generation program. Similarly, test vectors produced by the Automatic Test Generation Program can be run in the simulator to verify their correctness. Finally, test vector files for the physical testing of a chip design can be obtained by porting the MASM test vector files to the format needed by a commercial chip tester. Figure 3.15 shows the format of a MASM test vector file.

Simulation results can be presented in either a numeric mode on the message screen or as a screen-based output which can show individual signals in both a tabular and waveform type format. Numeric outputs to the message screen are obtained by using the **RUN_VECTORS** command on a set of simulation test vectors which have already been produced in MASM file format. To produce screen-based outputs a formatted screen must be set up for use as detailed in Chapter 4 of Reference 17. Figure 3.16 and Figure 3.17 are examples of the message and formatted screen type results which can be obtained.

To accomplish simulation of the DFT_CHIP, check functions were written and used to allow simulation steps to progress in an automated manner. Two categories of check

functions were written. Basic building block type check functions were written to accomplish limited simulation tasks. These check functions are also convenient for use during manual interactive simulation sessions. High level check functions were then written to automatically accomplish a complete simulation test by sequentially calling a set of the basic check functions.

The following basic building block check functions were written and used during simulation on the DFT_CHIP:

1. **MSP** - function to set the mask register values in a parallel manner.
2. **RSP** - function to set the reference register values in a parallel manner.
3. **DSP** - function to set the data register values in a parallel manner.
4. **TSS** - function to serially load 32 bits of data into the scan path.
5. **TS** - function to serially load one to 32 bits of data into the scan path.
6. **SS** - function to serially shift data into the data, reference, and mask registers and optionally at the same time load data into the scan path.
7. **force_in** - function to force values from the scan path latches into the data latches of the testability latches.
8. **swap_in** - function to swap the contents of the data and scan path latches in the testability latches.
9. **sample_in** - function to sample and replace the scan path latch values with the data latch values in the testability latches.
10. **LSE** - function used to assign the next bit of data which will be serially loaded via the serial input pin.

11. **tog** - function to set up toggle patterns for the clock signals.
12. **untag** - function to untoggle the clock signals.

The complete GENIE language code written for these check functions is contained in Appendix A.

Complete functional simulation testing of the DFT_CHIP was accomplished using the following high level check functions:

1. **initall** - function to initialize the values present at all input and output pins of the chip.
2. **test_parallel_in** - function to test the chip during parallel load operations.
3. **test_serial_in** - function to test the chip during serial load operations.
4. **test_force** - function to check force operations after serial loads of the scan path.
5. **test_scan_clock** - function to test the ability to operate the local scan path clock at a faster rate than the global system clock and to test the ability to conduct scan path operations during periods that the global system clock is not operating.

Each of these functions includes the traceobj command to produce MASM test vector files. The complete code written for these check functions is contained in Appendix B. These check functions were used to verify the functional operation of the chip using both GFL and GSL models. The results from these simulation operations indicated that the DFT_CHIP would function as desired once it was fabricated.

2. Timing Analysis

Genesil's Timing Analyzer feature provides an easy to use means of evaluating the timing characteristics and

relationships of a chip design. It uses algorithms, which do not need or make use of test vectors, to produce reports on the following timing characteristics [Ref. 18:p. 1-1]:

- Maximum operating speed
- Speed limiting paths within the design
- Constraints on duty cycles
- Input setup and hold times
- Output delays
- Signal delays, setup, and hold times for internal nodes
- Path delays between internal nodes.

Through an examination of these reports changes can be made to a design to help insure that it will operate without timing problems. Also, this information can be used to optimize chip speed performance for a design which is required to operate in an environment needing a specific minimum operating frequency.

For the DFT_CHIP design the main use of the Genesil Timing Analyzer was to verify that there were no timing relationship conflicts and to determine the anticipated maximum operating frequency for both clock signals on the chip. Since chip size not operating frequency became an overriding design criteria, the timing information was not used to redesign the chip layout to provide increased chip speed. However, it was used to gain information on the maximum anticipated clock frequencies. These clock frequencies were then specified for the clock signals during the netlisting process. Doing this insured that the compilation process would produce a fabrication layout able to handle the maximum clock frequencies calculated by the Timing Analyzer

for the specific signal paths and internal components of the DFT_CHIP.

Three specific Timing Analyzer reports were looked at for the DFT_CHIP. First, the **CLOCKS** command was issued to generate a **Clock Report**. This report provides details on the maximum operating frequency and duty cycle limitations for a particular clock signal. Included is information on the minimum high phase times for the internal nonoverlapping phase signals derived from the clock signal, the minimum nonsymmetric and symmetric clock signal times, and details concerning the worst case paths for each of the phases of the clock signal [Ref. 18:p. 5-4]. Second, the **SETUP_HOLD** command was used to generate a **Setup and Hold Mode Report** which indicates the setup and hold times needed for each input signal relative to the falling edge of the clock signal [Ref. 18:p. 6-1]. Finally, the **VIOLATIONS** command was issued to produce a **Violations Report** which indicates if any internal hold time violations exist for the design configuration produced [Ref. 18:p. 11-1]. It is a Genesil requirement that a Violations Report be generated and checked for all Genesil chip designs prior to design tapeout for fabrication to insure that the design will not experience internal timing problems after return from fabrication [Ref. 18:p. 11-1].

Since there are two different clock signals utilized for the DFT_CHIP, all three timing analysis reports had to be run twice. Based on the information obtained from these

reports the maximum expected operating frequencies for the DFT_CHIP were 4.43 MHz for the global system clock signal CLOCK and 28.6 MHz for the local scan path clock signal CLOCK2. Appendix C provides the complete timing analysis reports generated for both clock signals.

D. AUTOMATIC TEST GENERATION AND FAULT COVERAGE

The usage of Genesil's **Automatic Test Generation** (ATG) feature was extremely important to the work done for this thesis. It allows an exploration into the need for and effects of including DFT features in a chip design. The ATG feature provides a method to automatically generate test vectors which will uncover defects that occur due to the manufacturing (not design) process. ATG looks at manufacturing defects in terms of stuck-at 0 and stuck-at 1 faults. By running ATG for an object under design, test vectors are developed to uncover these stuck-at faults. Through a process of fault grading, ATG also determines the fault coverage for the test vectors it develops. When properly enabled, the ATG feature will produce a set of maximum possible fault coverage test vectors for the current design configuration of the object being developed. Therefore, by examining the achievable fault coverage level for an object, the effects of including DFT features into a design are quickly determined.

[Ref. 19:p. 1-1]

Genesil produces its fault coverage results through use of the classical D algorithm. This algorithm provides an algebra

for simplifying the computational tasks of testing for faults within a design. The D algorithm utilized by Genesil uses a process called **justification** to determine the inputs to apply to the design and a process called **sensitization** to check the outputs which will result for a specific sequence of events. [Ref. 19:pp. 1-2, 1-3]

Justification is related to the controllability of being able to set the inputs of a gate to specific values. The ATG justification process places desired values on the gate under test and then tries to back these values out of the circuit to primary inputs. If this process of backing the values out of the design is successful without producing any conflicting values on the primary inputs then the stuck-at test for that gate is said to be justified and the inputs to the gate are determined to be controllable.[Ref. 19:p. 1-4]

Sensitization is closely related to the observability of a circuit. It is the process of propagating the output of a gate being tested to a primary output of the circuit. If this is accomplished then the stuck-at test for the gate is said to be sensitized and the design configuration allows for observability of the output node of the gate.[Ref. 19:p. 1-4]

During the ATG process, Genesil first accomplishes an initial pass over the design to locate any faults which are obviously untestable and also to develop a testing priority to conduct tests first on those nodes which have the highest degree of observability and controllability. To speed the

test process, ATG uses a modified breadth-first search to look simultaneously at multiple paths to the primary inputs and outputs. ATG takes a single step along a given path during an evaluation of justification or sensitization, checks and puts the results for that path and step onto a list of pending processes, and then moves to the next path possible for that particular step. This causes a gradual expansion of the test process at each step. By doing this rather than checking just one path at a time, conflicts caused by any incompatible assertions, which may result during the justification and sensitization process, are recognized quicker. This helps to speed up the rate at which the overall ATG process can be accomplished. [Ref. 19:p. 1-7]

The penalty paid for the speed up possible from doing the breadth-first search is that if a conflict is found ATG has to retrace its steps all the way to the test assertion that caused the conflict. Then, all justification and sensitization evaluations must be repeated between the point of the assertion and the location at which the conflict was discovered. In doing this, paths not related to the conflict also are forced into being rechecked. To minimize the amount of work that needs to be redone, ATG partitions assertions into different search groups that it organizes based on a determination of which portions of the circuit are independent from each other. Therefore, a conflict in one search group does

not extend the need to rework justifications or sensitizations into another search group.[Ref. 19:p. 1-8]

Since the test algorithm used by the ATG process is trying to back justifications out of or propagate sensitizations through a circuit, sequential logic may present problems during the development of a test strategy. To handle sequential circuits the ATG process utilizes a method called **time unrolling**. This method has the effect of translating sequential circuit elements into combinational circuit elements that are examined over a restricted time range. This translation process can be viewed as producing a three dimensional set of combinational circuits where the third dimension is related to the number of timepoints that originate from the feedback path of the sequential circuit. The time window for the number of timepoints considered during the ATG process may be either a default based on Genesil's determination of the sequential depth of individual nodes in the object or it may be limited to a user specified number. The higher the number the slower the ATG process will proceed, but a higher number may produce a greater fault coverage or a denser maximum fault coverage test vector set.[Ref. 19:pp. 1-6, 1-7]

To run the ATG process on an object the following parameters from the ATG Control section of the ATG form must first be specified:

1. **Output File** - specifies the file to which the test vectors produced by ATG will be written.

2. **Sequential Depth** - determines the maximum number of timepoints which can be used to try and instantiate a specific fault test. Using the parameter of -1 provides a default for each node based on the shortest path from the node to a primary output.
3. **Random Input Vectors** - determines the number of random seed vectors the ATG process will generate and use as inputs. Using random input vectors may speed up the ATG process. Choosing a parameter of -1 will provide the same number of random vectors as the maximum sequential depth found in the object.
4. **Initialization Vectors** - determines the number of vectors from the Input File which will be run as simulation only to provide an initialization effect for the object. These vectors will not be included in the output test vector file. Any remaining vectors from the Input File will have the normal ATG process run on them.
5. **Default Toggles** - determines if the default toggle definition will be used for the clock signal in the circuit. Selecting NO will cause the clock toggle definition to be obtained from the Startup File if it exists.
6. **Limit Time** - determines the time limit (in CPU time usage) for which the ATG process will run. Selecting NO specifies unlimited time (although the ATG process may still quit if it is not able to instantiate a fault test after running a large number of test vectors).
7. **Limit Coverage** - selecting YES and specifying a fault coverage value will halt the ATG process when that fault coverage value has been obtained. Selecting NO indicates a default of 100 percent fault coverage.
8. **Fault Grade Only** - selecting YES allows the previously generated set of MASM test vectors specified as the Input File to be fault graded.
9. **Enable Input File** - selecting YES and specifying a file name provides the file to be used during either the initialization process or the file to be fault graded.
10. **Enable Startup File** - must be selected as YES and have the Startup File name provided for cases where the Default Toggles parameter is set to NO. The Startup File contains the clock toggle definitions which will be used to replace the default toggle definition. All chips with two or more clocking regimes must specify the clock toggle definitions in a Startup File. Reference

19, Appendix B provides examples of the toggle definitions which can be written for chips with multiple clocking regimes.

11. **Enable DFT File** - determines if a DFT file will be used to specify artificial primary inputs, outputs, and no connects. This feature allows the designer to specify additional inputs and outputs at internal circuit locations during the initial design process to help determine if including DFT features will raise the fault coverage possible. Select NO for this parameter for final chip testing using the ATG process.
12. **Enable Coverage In** - selecting YES causes the ATG process to consider a coverage map from a previous ATG run when it starts the present run. Coverage maps are files which provide the ATG process information on which faults remain to be tested in a design.
13. **Coverage Output File** - specifies the name of the coverage map file to which coverage information will be written.

Once all ATG Control section parameters are specified the ATG process is started by selecting **RUN_ATG** from the menu of the ATG form. [Ref. 19:pp. 4-4 - 4-7]

Once the ATG process is running its current status can be displayed in the ATG Status section of the ATG form. To update the status to the present time select the **UPDATE_SCREEN** choice from the ATG form menu. As an alternative, the status can be continuously updated and displayed by issuing the command **update_loop** at the ATG form command line prompt [Ref. 19:p. 4-11]. The ATG process runs in the background. This allows other Genesil activities to be performed while waiting for ATG to complete unless the status is continually being updated via the **update_loop** command [Ref. 19:p. 4-2]. Figure 3.18 shows a complete screen view of the ATG form, to

include the ATG Control and Status sections, for an example case of running ATG on the DFT_CHIP.

Upon completion of the ATG process (through either expiration of the specified time limit, achievement of the specified fault coverage level, or completion of fault grading for an input test vector set) the final results can be examined in depth by selecting the **ANALYZE** command from the ATG form menu. If the ATG process has not yet finished, it can be forced to stop by choosing the **HALT_ATG** command from the ATG menu. The ANALYZE command will then provide results based on all tests made prior to the halt being issued. Once ANALYZE is chosen a new menu is presented which allows the fault coverage statistics to be examined from the top level of chip down to the individual gate level. At the gate level the individual stuck-at faults which have or have not been tested are listed. Examination of this information provides the details on what portions of the design contains gates which the ATG process has not been able to fault test. Based on this information the design can be modified or DFT features can be included to raise the fault coverage obtainable. Figure 3.19 is an example for the DFT_CHIP of the format and type of information which can be provided by using the ANALYZE command. [Ref. 19:p. 5-2]

The starting use of the ATG feature was to look at the characteristics of the BASIC_CHIP design. First, the ATG process was run, with no limits on either time or fault

Figure 3.19 Fault Coverage Information Obtainable from using ANALYZE Command

coverage, to determine the maximum fault coverage obtainable for the design without DFT features. Once the test run reached a stage where additional test vectors were producing no increase in fault coverage the program was halted and the coverage obtained was examined using the ANALYZE command. Table IV presents the fault coverage results for BASIC_CHIP design in terms of its individual modules. Also included is the number of test vectors needed to achieve the fault coverage listed. The results listed for \$dummy come from a dummy module that the ATG process creates to contain artificial/dummy constructs used during the evaluation of certain types of Genesil blocks [Ref. 19:p. E-5]. These dummy constructs are needed to account for differences between the models generated by the Genesil simulator and the additional internal nodes created by the mapping of these models into the primitives used by Genesil during the ATG process. Therefore, the \$dummy results need to be included and considered when evaluating the fault coverage of a complete, top-level design.

As can be seen from Table IV, the modules with the lowest fault coverage were the combiner, input pad and \$dummy modules. Since the \$dummy module is based on a mapping of the simulation models for Genesil blocks to the primitives used by ATG, there is no way to identify how to improve this module's fault coverage without changing the components of the circuit design. Similarly, the fault coverage for the input pad modules is a function of the pad specifications and was not

TABLE IV

observed to change unless the type of input pads utilized was changed.

For the combiner module the ANALYZE command was selected and this module was looked at down to the gate level to try and determine which gates were not being completely tested. Based on this examination it was found that each of the four identical combiner module sections, used to convert a 4-bit wide slice of results coming from the xnorreg module output to a 3-bit number representing the sum of correlated bits, had the same gates with faults not tested. These are the gates labeled OR0, OR1, XOR4, XOR5, AND4 and AND5 in Figure 3.4.

Knowing which gates were not being completely tested, a decision could be intelligently made about where to place a scan path to help increase fault coverage for the combiner module. As previously discussed, the DFT_CHIP design was made by inserting a scan path made from testability latches in between portions of the original combiner module. As shown in Figure 3.5, the insertion location of the scan path in the combiner module was just prior to the incompletely tested gates along the direction of circuit propagation. It was hoped that by being able to scan in specific test vector sequences the ATG process would now be able to fault test some of the previously untested gates.

The ATG feature was then used to determine the fault coverage possible for the DFT_CHIP design. The results for the ATG test run, obtained using the ANALYZE command as per

Figure 3.19, are shown in Table V. As indicated, the inclusion of the scan path had a positive effect in several areas. First, the fault coverage for those gates not completely tested in the combiner module of the BASIC_CHIP design went up. The DFT_CHIP design was now able to test for faults on all of the gates from the combiner1 module and 92.5 percent of the gates from the combiner2 module. Since the sum of these two modules contains the same exact gates found originally in the combiner module of the BASIC_CHIP design, the result of including the scan path was to increase the fault coverage for the total combiner gates from 83.3333 percent to 96.8750 percent. Next, the scan path was able to raise the fault coverage for both the adder module (which is downstream in terms of circuit propagation from the scan path) and the \$dummy module to 100 percent. Most importantly, the overall fault coverage of the complete chip was raised from 87.4555 percent in the BASIC_CHIP design to 93.7295 percent in the DFT_CHIP design. Finally, the inclusion of the scan path not only raised the fault coverages obtainable but also lowered the number of test vectors needed to obtain the maximum fault coverage. It took 530 test vectors to obtain the maximum possible fault coverage for the BASIC_CHIP design but only 363 test vectors for the DFT_CHIP design.

Based on these results, the inclusion of the scan path had a considerable effect on the testability of the correlator chip. Due to the decreased number of test vectors needed to

TABLE V

obtain maximum possible fault coverage, the time used for testing of the DFT_CHIP after fabrication should be minimized. Perhaps more importantly, the increase in the overall fault coverage should lower the defect level found among chips that successfully pass the testing process. Using equation (1.7) as a basis for determining defect level, Figure 3.20 shows a plot of the defect levels for varying yields using the maximum fault coverage percentages of the BASIC_CHIP and DFT_CHIP designs. This shows graphically the gain, in terms of lower defect levels for the same yield, obtained from including a scan path in the design.

It should be noted that there are also two main penalties incurred by including the scan path which are representative of the effects of including a DFT structure into any design. First, the scan path itself introduces gates into the design which then have to be fault tested. The difference between the BASIC_CHIP design and the DFT_CHIP design was the inclusion of gates resulting in an additional 734 faults to test. For the correlator chip design this was over a 50 percent increase. A more complex design would have a smaller percentage increase for a scan path with the same number of testability latches but it could still be significant. A more complex design might also need more testability latches to produce a scan path able to raise fault coverage to a desired level. Secondly, the inclusion of a DFT feature like a scan path incurs a size penalty for the chip layout due to the

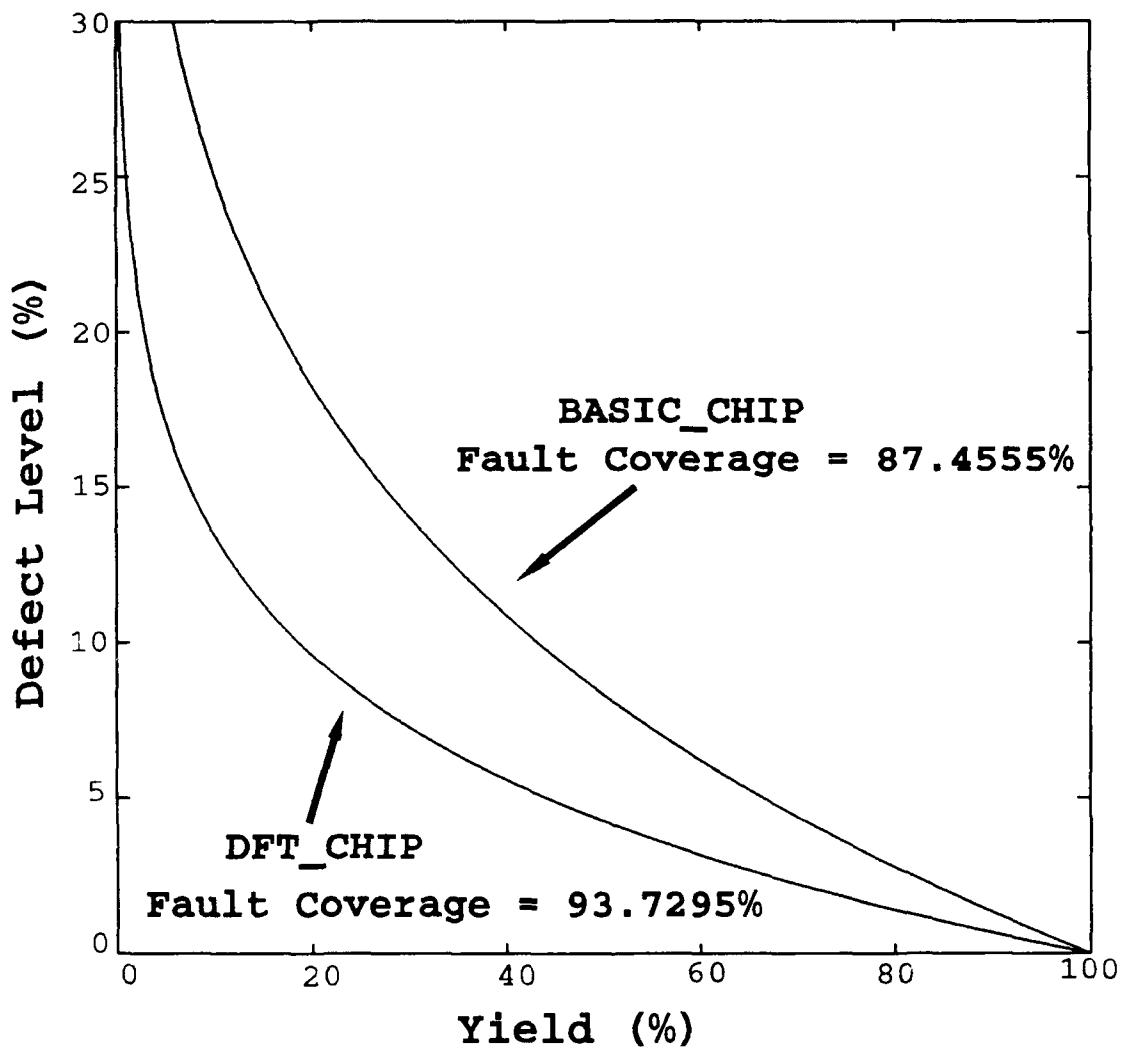

Figure 3.20 Defect Level versus Yield Using Maximum Fault Coverages of the DFT_CHIP and BASIC_CHIP Designs

additional gates needed. Since the BASIC_CHIP design was not optimized for size the same way the DFT_CHIP design was, no direct comparison can be made for these two cases. However, the size increase will be related to the number of additional gates used to include a DFT feature. Therefore, within an order of magnitude, the percentage increase in gates should be related to the percentage increase in total chip size. Additional penalties which might be experienced for including a DFT feature like a scan path include additional power consumption and possible lower limits on maximum clock speed.

The final use of the ATG feature was to look at the fault coverage levels obtainable from the test vectors used to check the functionality of the DFT_CHIP design. Each of the MASM test vector files produced during the simulation process using the four high level check functions (test_parallel_in, test_serial_in, test_force, and test_scan_clock) were fault graded using the ATG feature. Table VI shows these results. The results show that test vectors which are used to check the proper logic or functionality operation of a chip may not be very good for insuring a high degree of fault coverage. This demonstrates the need to test a chip using test vector sets which both look at the functionality issue and those which provide the maximum possible degree of fault coverage.

TABLE VI

test_force	725 of 2137	33.9261
test_scan_clock	408 of 2137	19.0922

IV. FABRICATION AND TESTING

Once a Genesil chip design has been completed (including all aspects of floorplanning, simulation testing, timing analysis, ATG processing and final compilation) it is ready to be sent for fabrication. This chapter first examines the steps taken to have the DFT_CHIP design fabricated through the MOSIS Service. Upon completion of fabrication, chips need to be tested to both validate that no functional errors exist in the design and that no manufacturing errors occurred during the fabrication. The second section of this chapter provides details on the test gear and testing process used to conduct this testing on fabricated copies of the DFT_CHIP design.

A. FABRICATION METHODOLOGY

The DFT_CHIP design produced for this thesis was fabricated through use of the MOSIS Service. MOSIS stands for MOS Implementation System and the MOSIS Service provides fabrication services to university classes, government agencies and government contractors under sponsorship of the Defense Advanced Research Projects Agency (DARPA) and the National Science Foundation (NSF) [Ref. 20:p. 3]. The MOSIS Service provides an inexpensive means of fabrication for standard cell and full-custom VLSI designs using 3.0, 2.0, 1.6 and 1.2 micron double metal CMOS technologies [Ref. 20:p. 1]. Multiple fabrication line vendors are utilized to manufacture

designs, and costs are kept down for MOSIS users by combining projects from several users onto a single wafer during fabrication runs [Ref. 20:p. 1]. Instead of paying between \$50,000 and \$80,000 for a complete wafer lot to be produced, users pay for only that percentage of the silicon space on the wafer that their designs occupy resulting in chips which can be fabricated for as little as \$400 [Ref. 20:p 1].

Actual charges for chip fabrication depend on which of the four MOSIS size categories the chip falls into. The four MOSIS size categories and the maximum sizes allowed for them are: tiny (2.3mm by 3.4mm), small (4.6mm by 6.8mm), medium (6.9mm by 6.8mm) and large (7.9mm by 9.2mm). As previously discussed, the DFT_CHIP design was limited to fitting within the MOSIS small size category due to budget constraints.

For Genesil designed chips being sent to MOSIS for fabrication there are two steps which must be taken prior to final compilation that differ from normal Genesil design practices. The first step involves the placement of pads for the chip during the pinout process of floorplanning. MOSIS highly recommends that designs should have the same number of pads located on all four sides of the cavity well, and that along each side the pads should be spaced approximately the same distance apart. This placement configuration may be slightly stricter than that encountered for designs not being fabricated through MOSIS. MOSIS requires this type of placement to insure that the bonding wires to the pads will

not be excessively long, cross, or be at too great a bonding angle. Secondly, a Genesil chip design sent to MOSIS should have the **NO_PACKAGE** option chosen for it in Genesil vice choosing a package type and attaching the bonding wires during pinout as is normally done.

MOSIS will have all chips submitted for fabrication packaged and will provide a bonding diagram with the fabricated chips. The package type used by MOSIS depends on the number of pins the submitted chip design has. Dual In-line Packages (DIP) are used for 28, 40, or 64 pin designs, and Pin Grid Array (PGA) packages are used for 84, 108, or 132 pin designs [Ref. 20:p. 57]. Additional information on MOSIS pad placement requirements and packaging practices is contained in Chapter 9 of Reference 20.

Once a Genesil design has been completed there are several additional tasks which need to be accomplished before submitting the design to MOSIS for fabrication. First, an account must be established with MOSIS to pay for the fabrication services. Universities which teach VLSI design may apply for government sponsored funding of their VLSI design projects [Ref. 20:p. 12]. This funding method was used for the DFT_CHIP design with funding being obtained via the NSF.

Secondly, the MOSIS fabrication schedule must be checked to find a fabrication run being done using a fabrication line technology available in Genesil. MOSIS fabrication runs occur approximately every two weeks with runs alternating between

3.0 and 2.0 micron feature sizes and p-well and n-well technologies. MOSIS has 1.6 and 1.2 micron feature size runs on-demand as enough projects to fill the runs are received.

Genesil offers over 20 different combinations of fabrication line vendors, feature sizes (ranging from 1.0 to 3.0 micron), and n-well or p-well process to choose from. A match must be made between a vendor, feature size and process type of a fabrication run scheduled by MOSIS and the same combination from among the Genesil choices. Since the MOSIS fabrication schedule does not list the fabrication line vendor which will produce a run, a phone call must be made to MOSIS to obtain this information.

Having determined a match between a technology combination available in Genesil and also scheduled by MOSIS, the Genesil design must be completely recompiled in the chosen fabrication line technology if a different technology was previously specified. It should be noted that this can have an effect on the size and operating speed of a design so ideally a match should be determined early in the design process. Doing so will avoid the need to review the chip parameters once a chip design is completed. If a change must be made for the fabrication line technology, the only penalty within Genesil is the several hours of CPU time needed to completely recompile the chip. No other changes are needed within Genesil to change from one fabrication line technology to another. The compiled design layout produced by Genesil will utilize the

specific design rules for the fabrication vendor of the fabrication line technology chosen.

Upon completion of these steps the Genesil design must be exported from the Genesil system into a file which can be sent to MOSIS. To export a Genesil design the following steps need to be taken from within the Genesil operating environment.

1. Select the chip to be exported as the current object and return to the Genesil main menu.
2. Select **TOOLING** and then **TAPEOUT** from the Genesil menus.
3. Select **SIZING** or **NO_SIZING**. **SIZING** produces foundry customized data based on the design rules of the fabrication line foundry specified while **NO_SIZING** produces a generic type layout [Ref. 15:p. 11.18]. Not all fabrication line vendors utilize sized layouts. Since the present documentation does not provide information on which fabrication line technologies need to be sized, a phone call to the Genesil Silicon Compiler Corporation may be needed.
4. Choose **CIF** (Caltech Interchange Format) as the file format to be used to specify the layout. Genesil also offers **GDSII** (Calma Corporation GDSII Stream Format) but MOSIS requires submissions be done using the **CIF** format.
5. Specify the filename for the **CIF** file. Genesil will then create the **CIF** file within the Genesil environment as either a type **HCF** file (for unsized **CIF**) or a type **CIF** file (for sized **CIF**).
6. Export the file from the Genesil environment by selecting **ANCILLIARY_FILE**, **EXPORT_FILE**, choosing the file to export, and providing a filename to which the exported file will be written.

These steps will result in a **CIF** file of the chip design being exported to the UNIX directory from which Genesil was started.

The final step to be taken before submitting the design is to run the **CIF** file through the MOSIS **CIF_CHECKSUM** program which can be obtained from MOSIS in "generic" C source code

format. The purpose of the CIF_CHECKSUM program is to compute a checksum for the CIF file to help insure the accuracy of transmission process used to send the file to MOSIS. Due to the large size of CIF files (918K for the DFT_CHIP design) and the catastrophic result of errors, MOSIS requires that the checksum value be computed and provided along with all design submissions.

All interaction with MOSIS is normally done using electronic mail via the INTERNET computer network. Electronic mail correspondence to MOSIS must be done using formatted messages. This includes requests for information, identification of project information, submission of CIF files and requests for project status. Chapters 4 and 13 of Reference 20 give specifics on the means and message formats which must be used during communications with MOSIS.

Genesil produced chips have layouts based on specific fabrication line design rules vice the MOSIS scalable design rules. The project information message must indicate that specific fabrication line design rules were used by stating the fabrication line technology chosen (VTI_SCI for the DFT_CHIP which used a VLSI Technologies, Inc. fabrication line) on the **TECHNOLOGY** line of the message. This information should also be noted by including a statement in the **ATTENTION** field that the chip was produced using fabrication line specific design rules.

To fabricate the DFT_CHIP design through MOSIS, all the steps discussed in this subsection were followed. Based on the MOSIS fabrication schedule, the VTI-CN20A 2.0um n-well process from VLSI Technology, Inc. was chosen as the fabrication line technology for the chip. Based on this choice, the key parameters listing developed by Genesil for the DFT_CHIP design is shown in Figure 4.1. MOSIS was able to fabricate and return the DFT_CHIP design within eight weeks of the original design submission. The cost of chip fabrication was \$2200 for 12 copies of the chip. Figure 4.2 is a reproduction of a picture taken by MOSIS of the actual chip which was fabricated.

B. TESTING METHODOLOGY

The final step undertaken in the development process for this thesis was the physical testing of the chips which were fabricated via MOSIS. Only by actually applying signals to a chip and observing its outputs can the functionality requirements and fabricated implementation of the design be finally validated. During the testing process, test vector sets were applied to the fabricated DFT_CHIP design to both verify the operational functionality of the chips and to check for improper chip operation which could have originated from errors during the fabrication process. Testing for operational functionality was used to validate the Genesil simulation results previously obtained for the chip. Testing for any manufacturing errors which occurred during fabrication was

accomplished by applying the maximum fault coverage test vector set produced by the Genesil ATG process. Finally, testing was done on the chips to try and determine the maximum clock speeds which could be used for the fabricated DFT_CHIP design.

1. Testing Methodology for the DFT_CHIP Design

This subsection deals with the methodology used during the testing of the fabricated chips from the DFT_CHIP design. However, the approach taken and steps used is applicable to almost any other chip design produced using Genesil. The actual test facilities and test gear used to accomplish testing of the fabricated DFT_CHIP design chips involved usage of a commercial level chip tester, the **Textronix Digital Analysis System (DAS) 9100**, and its associated personal computer (PC) controller software.

The DAS 9100 is a commercial level tester which has numerous options for performing selected pattern generation and data acquisition functions and can be used in a stand-alone mode to accomplish chip testing. DAS 9100 Pattern Generation modules are used to apply input signal patterns to the device under test (DUT). DAS 9100 Data Acquisition modules are used to acquire the output results from the DUT and to monitor the input patterns supplied by the Pattern Generation modules.

Since testing on the DFT_CHIP was not done using the DAS 9100 in a stand-alone mode, its use in this manner will not be discussed here. Instead, the DAS 9100 documentation of

Reference 21 and Reference 22 should be reviewed for information concerning the configurations, capabilities, usage and setup of the DAS 9100 in a stand-alone mode. Additionally Chapter III of Reference 23 should be read to gain information on usage of the DAS 9100 configuration available at the Naval Postgraduate School (NPS).

Testing of the DFT_CHIP design was done exclusively by using the DAS 9100 in conjunction with its PC controller based **9100 Device Verification Software (91DVS)**. The advantage of performing testing in this method vice using the DAS 9100 in a stand-alone mode is the ease of use and speed of configuration setup possible for performing testing on the DAS 9100. Through use of a menu driven interface, the 91DVS software allows the user to send setup commands to the DAS 9100, apply test sequences to run tests, compare acquired test results against expected results and view the applied test patterns and acquired test results outputs along with the expected results on a screen display [Ref. 24:p. 1-1]. 91DVS can be run on any AT or XT configuration PC with DOS 3.0 or higher, and the PC is linked to the DAS 9100 via use of a GPIB interface card which controls a high-speed data link [Ref. 24:p. 1-1]. Figure 4.3 shows a functional block diagram of the NPS configuration for the test system utilizing the 91DVS software with the DAS 9100 tester.

The 91DVS software contains two software program choices for installation: DVS25 and DVS50. Based on the use

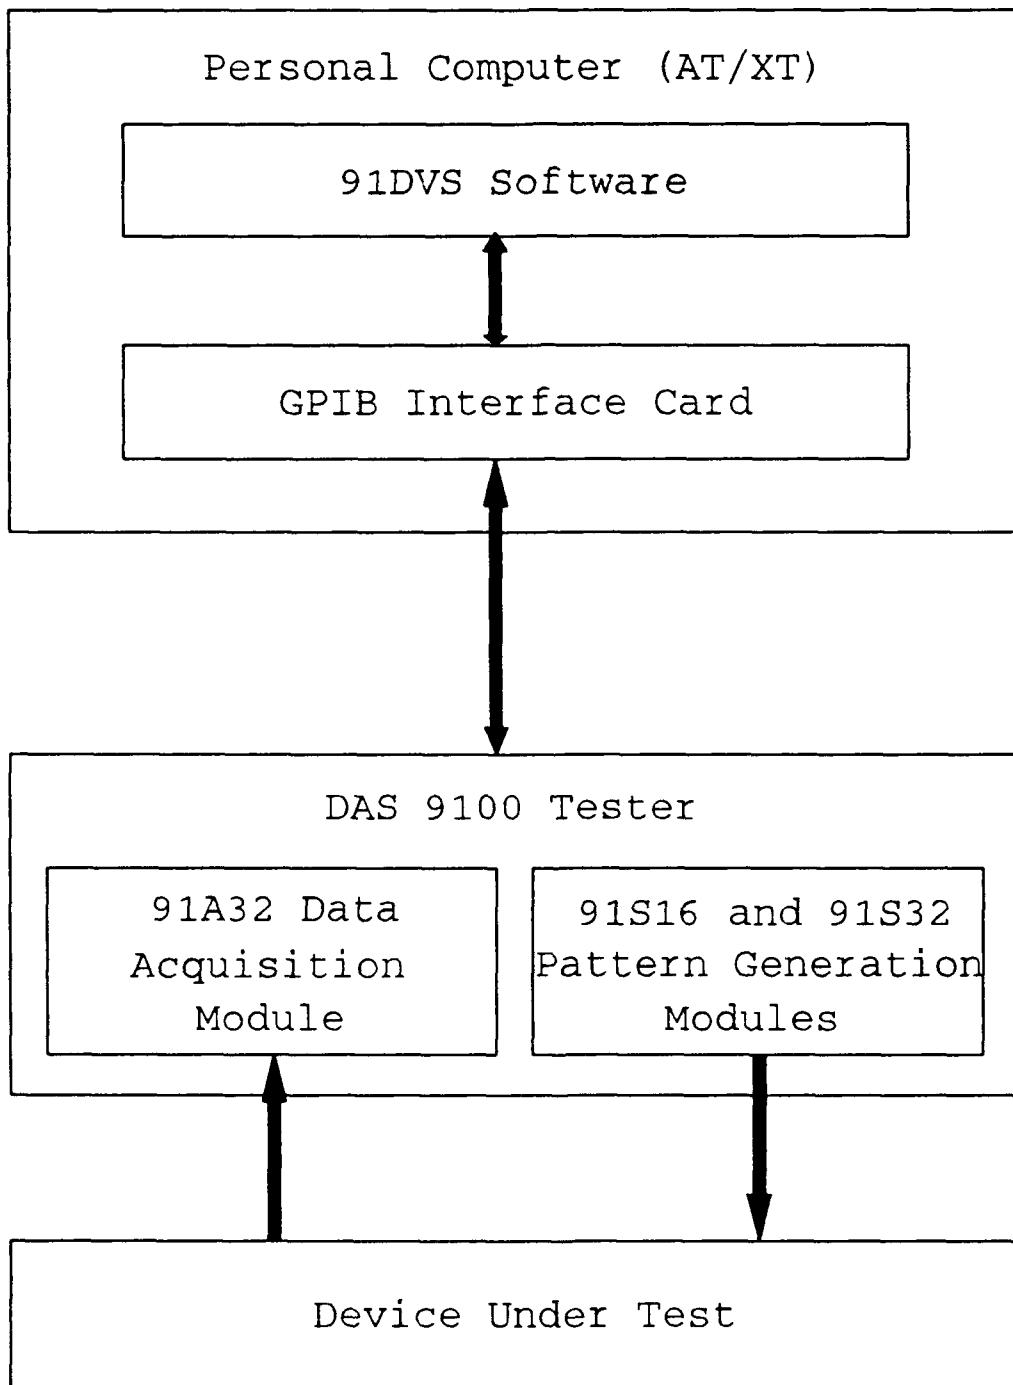

Figure 4.3 Functional Block Diagram of Integrated 91DVS and DAS 9100 Test System

of 91S16 and 91S32 Pattern Generator modules for the DAS 9100 configuration at the NPS, the **DVS50** software program is presently installed on the controller PC. Use of the DVS50 software requires that the clock rates for the pattern generator and data acquisition modules of the DAS 9100 be the same [Ref. 24:p. 1-3]. Since the DAS 9100 configuration at the NPS uses a 91A32 Data Acquisition module with a 25 MHz maximum clock rate, this limits the maximum clock speed of the pattern generator modules to this same rate. The additional DVS50 requirement that data acquisition modules be clocked from the output of a pattern generator module limits the present NPS DAS 9100 configuration of pattern generator and data acquisition modules to 31 data acquisition channels and 47 pattern generation channels [Ref. 23:p. 73].

To use the DVS50 software to run a test two user supplied files must be available on the PC: the ".src" file and the ".das" file. The ".src" file is used by the DVS50 software to generate the configuration setup information used by the DAS 9100 during the test run. The ".das" test pattern file contains the sequence of input signal test vectors which will be applied to the DUT. An additional file which can be used with the DVS50 software is the ".sim" file. It contains the sequence of test vector inputs together with the expected output signal results and is used to compare actual test results against the expected results. The ".src", ".das", and ".sim" files must all be generated prior to initiating use of

the DVS50 program. Chapter 5 of Reference 24 contains specifications for the required formats of these files.

The MASM test vector files generated by the simulator and ATG processes in Genesil are not in the format of the ".das" and ".sim" files used by the DVS50 program. Additionally, the ".src" file must be generated at least once for each fabricated Genesil design which will be tested. To simplify the process of creating the files required by the DVS50 program, a conversion program, **convert.c**, was written in C to translate Genesil MASM test vector files to the ".das" and ".sim" formats. Additionally, if generation of a ".src" file is requested the conversion program will query the user on the needed information to produce a ".src" file. The source code for convert.c is contained in Appendix D. Both the source code and the executable program, convert.exe, are contained in the C:\DVSTEST subdirectory of the PC which has the DVS50 program installed on it.

To produce the user files required by the DVS50 program the Genesil MASM test vector files must first be exported from Genesil to a UNIX directory and then be transferred to the C:\DVSTEST subdirectory of the PC by using the KERMIT file transfer procedure. The conversion program can then be run. To obtain instructions on the use of the conversion program just enter the command "convert" from the C:\DVSTEST subdirectory.

An example of the ".src" file which can be produced using the conversion program is shown in Figure 4.4. Each pin on the DUT, as identified by name and pin number, shows whether a pattern generation (PAT) channel, data acquisition (ACQ) channel, or both will be attached to it. Additionally, the power supply pins have the label PS identified with them. The ".src" file also contains the details on the pattern generator module clocking rate (TIMEDEF information), pin threshold level (THRESHOLD information) and power supply pin definitions (PSDEF information) used by the DVS50 program to establish the proper setup information for the DAS 9100.

Examples of the ".das" and ".sim" files are provided in Figure 4.5 and Figure 4.6. They are nearly the same except that the ".sim" file contains the names and expected output sequence results for each output signal as well as the input signal names and test vectors. The ".das" file contains only the input signal names and test vector information.

Once ".src", ".das" and ".sim" files have been created through use of the conversion program testing on a chip via use of the DVS50 software can commence. Reference 23 contains a detailed tutorial on the use of this software. The following steps used to test the fabricated chips from the DFT_CHIP design illustrate the testing process.

1. Start the DVS50 program by typing DVS50 from within the C:\DVSTEST subdirectory which contains the ".src", "das" and ".sim" files.
2. From the DVS50 main menu choose **Compile Test Program** and provide the names of the ".src" and ".das" files. The

DVS50 program will use these files to produce the binary information files used to setup and control the DAS 9100 during the test run. Additionally, the **Channel Specification List**, which indicates how to connect the DAS 9100 probes to the DUT, is produced.

3. Return to the main DVS50 menus and Choose **Information**. From the Information menu select **Printing** to toggle the information output location to send information to the printer vice the screen. Next select **List Channel Specification** from the Information menu. This will cause a copy of the Channel Specification List to be printed out. This step needs to be done only for the first test on a chip design or if anything as been changed in the ".src" for subsequent tests.
4. Using the information from the Channel Specification List insert the DUT in the test jig and connect the DAS 9100 probes and power supply connectors. Figure 4.7 is an example of the Channel Specification List information used to connect up the DUT. Changes to the probe connections for subsequent tests and additional chips only needs to be done if the ".src" file PAT or ACQ channel information has been changed.
5. Reenter the DVS50 man menu and choose **Enter Test Menu** followed by **Run Test** to commence the test run. Ensure that the DAS 9100 has its power turned on and has completed its startup self-checks. When prompted by the DVS50 program turn on the power to the test jig for the DUT. The DVS50 program will then download the configuration setup and test vector pattern information to the DAS 9100. The DAS 9100 will run the test using this information and upload the results from the data acquisition channels to the PC. The test results are stored on the PC by the DVS50 software in a file with the extension name of ".A01". Upon completion of the test turn off the power supply to the test jig and reenter the main DVS50 menu.
6. To display the test results on the PC's screen select **Display Test Results** and provide the filenames of the ".A01" and ".sim" files. The DVS50 program will display the test results in timing diagram format with the ".A01" file actual test result information and ".sim" file expected test result information overlaid on each other in different colors for easy comparison. The screen display window can then be expanded, compressed, or moved through in a left or right direction using the PC function keys. The screen display window can display information on up to 24 signals at a time. Initially the display will show the alphabetically first 24 input

Figure 4.7 Channel Specification List Format

or output signals acquired during the test. To see other signals one of the signals presently displayed must be deleted before another signal can be inserted for display. Chapter 4 of Reference 24 provides specifics on user control of the DVS50 screen display. Figure 4.8 is an example from a test on the DFT_CHIP design of the screen display format which can be obtained for looking at test results.

Additional chips of the same design can be tested against the same set of test vectors by merely replacing the chip located in the test jig and then re-entering the DVS50 test menu (i.e., start with step five above).

2. Test Results for the DFT_CHIP Design

Using the steps enumerated in the previous subsection (Testing Methodology for the DFT_CHIP Design), the fabricated copies of the DFT_CHIP design were tested on the Das 9100 test gear. Each of the 12 fabricated chips were tested for overall manufacturing errors caused during fabrication by applying the test vector pattern for the maximum fault coverage test vector set obtained from the Genesil ATG process. Next, to validate that the DFT_CHIP design functionality was consistent with the desired operational logic the chips were tested using the test vector patterns produced from the Genesil simulation process. Each chip was tested using the test vectors produced from the test_parallel_in, test_serial_in, test_force and test_scan_clock simulation check functions.

Since the logic design for all chips is the same and the purpose of the maximum fault coverage test vector set is to uncover manufacturing errors, the need to test the logic functionality of each chip in a commercial environment is not

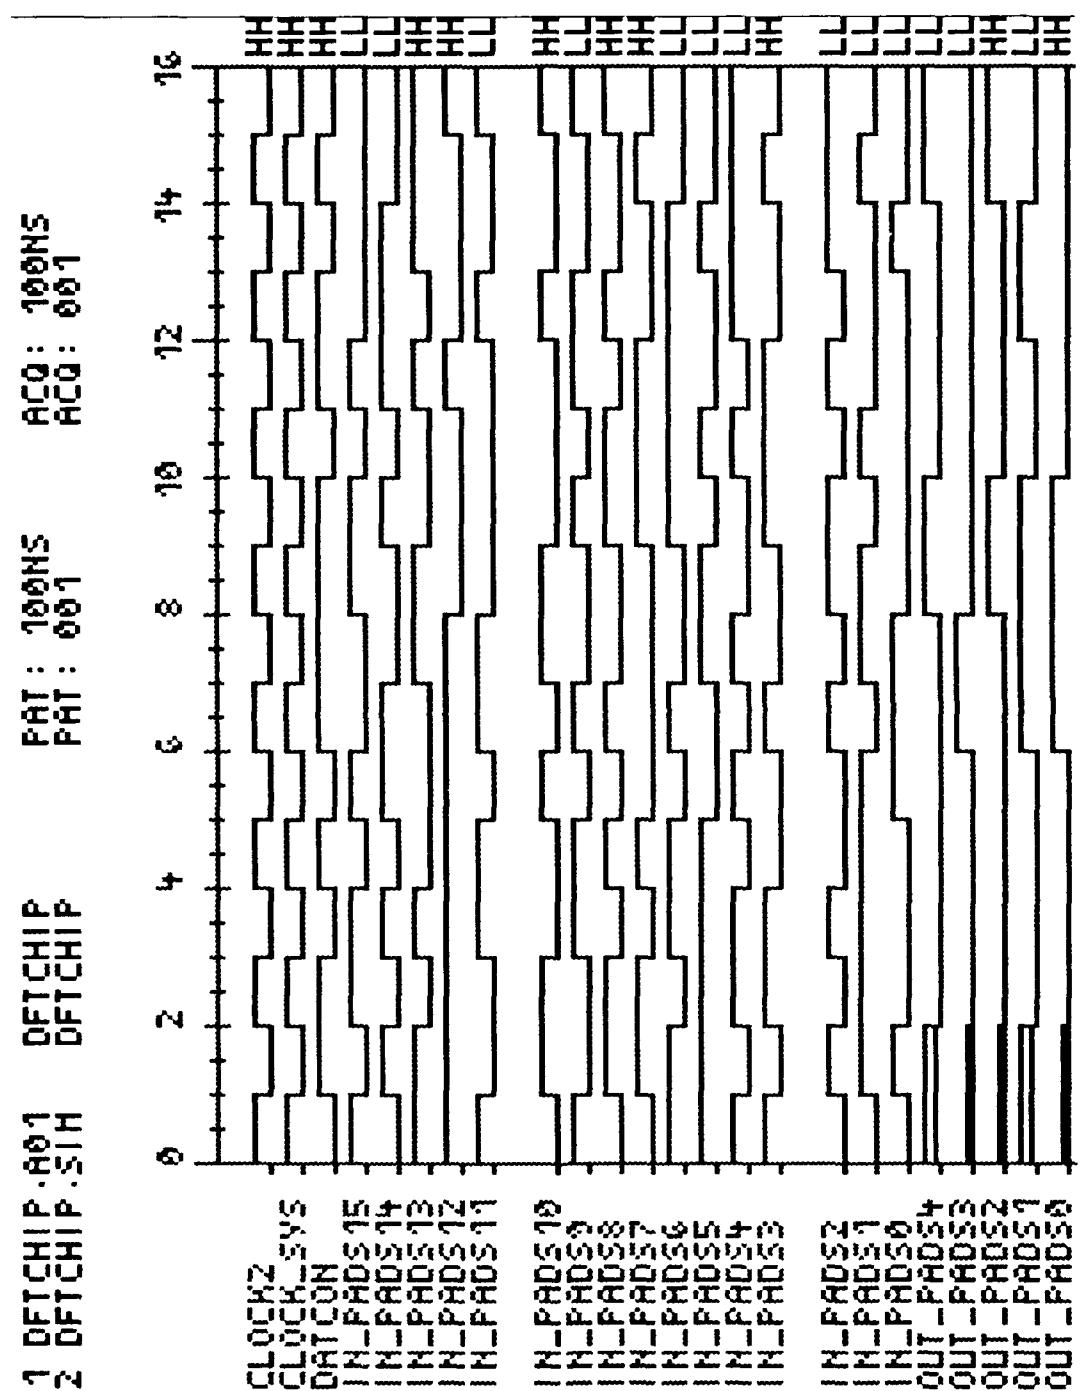

Figure 4.8 DVS50 Screen Display Format

present. Instead, if fault coverage is high, a commercial chip design may need to have only limited chip quantities checked for proper logic functionality. The remaining chips would then be accepted or rejected based only on the results obtained from testing with the maximum fault coverage test vector set.

For the DFT_CHIP design all copies of the fabricated chip passed all tests run on them. No unexpected logic functionality errors or manufacturing errors were observed. The DAS 9100 test gear, as controlled using the DVS50 software via the PC, made for a quick and easy means to conduct the tests and compare the results against the expected values determined by Genesil.

The final testing conducted on the fabricated chips was that done to try and determine the maximum clock speeds at which the two clock signals for the DFT_CHIP design could be applied. The global system and local scan path clock signals for the chip are generated via the test vector patterns which are applied. It takes a minimum of two consecutive test vectors to produce a complete clock cycle for either of these two signals. Since the DAS 9100 applies one test vector for each complete cycle of the pattern generator clock, the minimum time periods for the clock signals applied to the chip were twice the period of the pattern generation clock cycle used by the DAS 9100.

Using a 91A32 Data Acquisition module the DAS 9100 tester can have pattern generation clock cycle periods of 40ns, 50ns, 100ns, 200ns, 500ns, 1us, 2us, 5us, 10us, 20us, 50us, 100us, 200us, 500us, 1ms, 2ms and 5ms. Based on this, the maximum testable global system and local scan path clock speeds which could be applied to the DFT_CHIP design using the DAS 9100 configuration available at the NPS were 12.5 MHz. This same limitation would be found for any clock signal applied to a DUT that was derived from a Genesil produced test vector pattern.

First, the test vector sets which had both the global system and local scan path clocks cycling at the same speeds were applied to the chips. At clock speeds of 12.5 MHz and 10.0 MHz the chips would not produce the correct outputs. At a clock speed of 5.0 Mhz the outputs were correct.

Next, the test vectors produced from the test_scan_clock simulation function were applied. This function caused the global system clock signal to be first applied at a frequency half that of the local scan path clock signal and then to remain off while the local scan path clock continued to function. When this set of test vectors was run with the pattern generation clock frequency set such that the global system clock cycled at 6.25 MHz and the local scan path cycled at 12.5 MHz the outputs were as predicted.

These results tend to verify the predictions made by Genesil about the maximum operating frequencies for the two

clocks on the DFT_CHIP design. The maximum operating frequency for the global system clock is at least 5.0 MHz but is less than 10.0 MHz. The exact maximum operating frequency for the global system could not be determined since the DAS 9100 can only change test frequencies in set increments. However, the chips all performed better than the apparently conservative Genesil estimate of 4.43 MHz for the global system clock. The local scan path clock was able to run successfully run at 12.5 MHz which verified Genesil's prediction that it would run faster then the global system clock. Higher speeds for the local scan path clock could not be attempted due to the maximum operating speed constraints of the present DAS 9100 configuration. Finally, these results validated the design objective of being able to run the local scan path clock at a higher frequency than that of the global system clock and to continue scan path operations during periods that the global system clock was not operating.

V. CONCLUSIONS

A. SUMMARY

This thesis has both described the benefits of including Design for Testability in a VLSI chip design and provided information on accomplishing this using the Genesil Silicon Compiler. Through a presentation of the methodology needed to implement a DFT design using Genesil, fabricate the design via MOSIS, and then test the chips on the DAS 9100 tester, a complete chip design production and testing sequence was illustrated.

The need for including DFT features in chip designs becomes increasingly important as the maximum fault coverage obtainable for more complex chips without DFT features decreases. The need for obtaining a high degree of fault coverage for VLSI chips was examined and a relationship between a chip's fault coverage, defect level and yield was developed. Both the Scan Path and Built-in Test techniques were discussed. They both provide a reasonable means of raising the fault coverage possible for a chip by providing greater controllability and observability of internal chip nodes. Whether one and/or both of these techniques should be used is decided by incorporating an evaluation of the specific design being produced.

Genesil, through its Testability Latch Blocks, provides a simple means of incorporating DFT into a chip design. Due to its ease of use, Genesil allows different DFT alternatives, in terms of techniques and/or feature placement, to be evaluated in a reasonable amount of time.

Including DFT features in a chip design can exact penalties in both the chip size and in performance characteristics such as operating speed and power consumption. Genesil designs are especially prone to experiencing penalties in chip size as object components are added. Proper floorplanning techniques, to include manual placement to locate objects, is critical in the size optimization effort for a Genesil produced design.

Genesil's simulation and automatic test generation features provide an integrated, easy to use means of developing test vectors which will either check the logic functionality of a design or provide the maximum possible fault coverage. Fault grading using the ATG process illustrated that test vector sets which provide good functional testing information may not provide a high degree of fault coverage. This again demonstrates that both categories of test vectors are needed for testing purposes. Being able to use an automated approach to developing test vectors provides a significant time savings. Without the simulation and ATG features of Genesil the evaluation of test vectors to be applied to the fabricated chips, on top of all the other

necessary design development steps, would not have been practical for a single person to accomplish.

Once Genesil designs are finished they are completely compatible with fabrication via MOSIS as long as a match is made between fabrication technologies. MOSIS provides excellent turn-around time service at a very reasonable cost of fabrication.

By utilizing the DVS50 software to control the DAS 9100 tester, chips fabricated from Genesil produced designs can be conveniently tested. The conversion program to translate test vectors from Genesil's MASM file format to the ".das" and ".sim" files used by the DVS50 software provides an easy means of utilizing any test vectors produced during the design process. Almost no knowledge of the DAS 9100 tester is needed to conduct tests if the DVS50 software is used. The DAS 9100 provides an adequate means of testing fabricated chips within the limitations of the maximum chip clock speeds which can be obtained.

Simulation results predicted by Genesil agreed with the results obtained during actual testing on the fabricated chip design. The use of the scan path for the design raised the fault coverage obtainable and lowered the number of test vectors needed to obtain maximum fault coverage as compared to the same design without a scan path. Obtaining expected test results for the maximum fault coverage test vector set indicated, to a high degree of confidence, that all the chips

were properly fabricated. Without the scan path feature the degree of confidence about the absence of manufacturing defects would have been smaller.

B. RECOMMENDATIONS

The following recommendations should be considered for implementation or additional investigation:

1. Genesil usage is highly CPU intensive. For the present setup of Genesil operating on the VAX a large amount of time is wasted waiting for Genesil to complete operations during periods of medium to high computer usage by other students. To greatly increase the speed of producing Genesil designs, Genesil should be moved to a platform which allows nonshared usage of a fast CPU.
2. The speed of applying test vectors on the DAS 9100 using the DVS50 software is presently constrained due to using a 91A32 Data Acquisition module which has its acquisition rate limited to 25 MHz. A 91A08 Data Acquisition module, which would raise this rate to a 50 MHz limit using the DVS50 software, should be acquired. This would allow an effective maximum rate of 25 MHz, vice the present 12.5 MHz, for chip clock signals generated via Genesil produced test vector sets.
3. Investigate the use of the Built-in Test DFT technique alone and or together with a scan path on a more complex Genesil produced VLSI design.
4. Investigate the incorporation of integrated DFT techniques and features into multiple chip VLSI designs to enhance complete board and or system level testing.
5. Genesil designs are presently limited by the need to utilize only Genesil library provided blocks during the design process. Investigate the means of incorporating optimized VLSI components, designed in a program like MAGIC, into Genesil designs to enhance the performance of critical chip components and to minimize overall chip size.

APPENDIX A. BASIC CHECK FUNCTIONS

This Appendix contains the GENIE language source code written for the basic building block check functions. These check functions only accomplish limited simulation tasks but may be grouped together or called from a higher level check function to run a complete simulation test.

APPENDIX B. HIGH LEVEL CHECK FUNCTIONS

This Appendix contains the GENIE language source code written for the high level simulation check functions. These check functions use the basic level check functions to automatically accomplish a complete simulation test. Use of the Genesil traceobj command also causes these check functions to produce MASM test vector files.

```
func initall /* Function to initialize all input pins at time
-1. Note: all pins must have an initialization value
assigned for the simulation process to work
correctly. Also, note: prior to running this
function the time should be reset to time -1 by
using the command init toggles. */

APPENDIX C. TIMING ANALYSIS REPORTS

This Appendix provides the timing analysis reports generated for the global system and local scan path clock signals in the DFT_CHIP design. A Clock, Setup and Hold and Violations report was generated for each of these two clock signals. This information was used to verify that the DFT_CHIP design did not have any timing relationship conflicts and also to determine an anticipated maximum operating speed for both the global system and local scan path clock signals.

APPENDIX D. TEST VECTOR CONVERSION PROGRAM

This Appendix provides the C source code for the conversion program used to translate Genesil MASM formatted test vector files to the ".das" and ".sim" file formats used by the DVS50 software. The conversion program also interactively produces a ".src" file for use with the DVS50 software if the conversion program user indicates that this needs to be done.

```
*****  
convert.c - conversion program to take the Genesil ATG or  
SIMULATOR produced MASM test vector results from  
.SMO file format and translate it to the .DAS  
and .SIM formats used by the DVS50 software  
during testing on the DAS 9100 tester.  
Additionally, a .SRC file for use by the DVS50  
software is produced interactively if desired  
by the conversion program user.
